Evolve®

YOU'VE JUST PURCHASED MORE THAN A TEXTBOOK!

Evolve Student Resources for *Rifai: Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics, Eighth Edition*, include the following:

- Answers to Review Questions
- Case Studies
- The Coakley Collection of Clinical Cases
- Deacon's Challenge Biochemical Calculations Collection
- References

Activate the complete learning experience that comes with each
NEW textbook purchase by registering with your scratch-off access code at

EIGHTH EDITION

TIETZ FUNDAMENTALS OF

CLINICAL CHEMISTRY and MOLECULAR DIAGNOSTICS

Nader Rifai, PhD

Professor of Pathology
Harvard Medical School
Louis Joseph Gay-Lussac Chair in Laboratory Medicine
Director of Clinical Chemistry
Boston Children's Hospital
Boston, Massachusetts

Andrea Rita Horvath, MD, PhD, FRCPath, FRCPA

Professor (Honorary), School of Public Health
University of Sydney
Professor (Conjoint), School of Medical Sciences
University of New South Wales
Clinical Director, SEALS Department of Clinical Chemistry and Endocrinology
New South Wales Health Pathology
Prince of Wales Hospital
Sydney, Australia

Carl T. Wittwer, MD, PhD

Professor of Pathology
University of Utah School of Medicine
Medical Director, Immunologic Flow Cytometry
ARUP Laboratories
Salt Lake City, Utah

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary. Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility. With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

PREFACE

We are pleased to introduce the eighth edition of *Tietz Fundamentals of Clinical Chemistry and Molecular Diagnostics*. We built on the excellent work of our predecessors and used electronic tools to produce a state-of-the-art product for students, trainees, and practicing clinical laboratory scientists.

Chapters were extensively updated, and more than 60 new authors were recruited to present the most current and relevant information. We aimed to harmonize the presentation of information among chapters while retaining the personality and unique style of each author, hoping for a readable, educational text.

Unlike most other textbooks, all chapters in this edition were reviewed by three individuals: a reviewer, an associate editor, and a senior editor. We believe that these efforts have led to a better product. In addition, we made a concerted effort to create an *international* rather than an *American* product to reflect different practices from around the world; for example, all measurements are presented both in traditional and SI units.

In addition to the print format of *Fundamentals*, a wealth of supplementary educational materials including clinical case studies, biochemical calculations, multiple-choice questions, and references are available on the Elsevier Evolve platform for an enhanced learning experience.

This project has been a true group effort and represents the collective intellect, knowledge, and experience of approximately 120 leaders in laboratory medicine from 13 countries. We are in debt not only to the authors, reviewers, and editors of the chapters but also to the contributors of the supplementary materials that greatly enrich the product. We are grateful to Elsevier, and particularly to Laurie Gower, for supporting us throughout this project.

We sincerely hope that this product will be a valuable educational and reference resource for the clinical laboratory scientists' community worldwide.

Nader Rifai
Andrea Rita Horvath
Carl T. Wittwer

PART I Principles of Laboratory Medicine

- 1 Clinical Chemistry and Molecular Diagnostics, 1**
Nader Rifai, Andrea Rita Horvath, and Carl T. Wittwer
- 2 Analytical and Clinical Evaluation of Methods, 7**
Kristian Linnet, Karel G.M. Moons, and James C. Boyd
- 3 Preanalytical Variation, 38**
Ana-Maria Simundic
- 4 Biological Variation, 51**
Sverre Sandberg, Thomas Røraas, Aasne K. Aarsand, and Callum G. Fraser
- 5 Establishment and Use of Reference Values, 64**
Gary L. Horowitz and Graham R.D. Jones
- 6 Specimen Collection, Processing, and Other Preanalytical Variables, 77**
Doris M. Haverstick and Patricia M. Jones
- 7 Quality Management, 90**
W. Greg Miller and Sverre Sandberg
- 8 Principles of Basic Techniques and Laboratory Safety, 108**
Stanley Lo

PART II Analytical Techniques and Instrumentation

- 9 Optical Techniques, 127**
Larry J. Kricka and Jason Y. Park
- 10 Electrochemistry and Chemical Sensors, 145**
Paul D'Orazio
- 11 Electrophoresis, 167**
Lindsay A.L. Bazydlo and James P. Landers
- 12 Chromatography, 180**
David S. Hage
- 13 Mass Spectrometry, 201**
Mark M. Kushnir, Nigel J. Clarke, and Alan L. Rockwood
- 14 Enzyme and Rate Analyses, 215**
Renze Bais and Mauro Panteghini
- 15 Immunochemical Techniques, 236**
Larry J. Kricka and Jason Y. Park
- 16 Automation, 251**

Clinical Chemistry and Molecular Diagnostics

Nader Rifai, Andrea Rita Horvath, Carl T. Wittwer*

OBJECTIVES

1. Define the following terms:
 - Ethics
 - Laboratory medicine
 - Molecular diagnostics
2. List and explain the reasons for performing a laboratory test.
3. Describe the field of laboratory medicine, including subdisciplines, information handling, and ethical issues.
4. Describe the role of the clinical chemist.
5. Describe the possible career paths for the clinical chemist.
6. State the applications of molecular diagnostics in laboratory medicine.
7. List and explain five ethical issues that confront laboratorians; describe the critical importance of maintaining confidentiality in the laboratory.
8. Evaluate a possible confidentiality or conflict of interest issue and determine whether it is an ethics violation.
9. State the roles of authors, editors, reviewers, and publishers in providing high quality scientific publications.

KEY WORDS AND DEFINITIONS

Ethics Rules or standards governing the conduct of an individual or the members of a profession.

Laboratory medicine A component of laboratory science that is involved in the selection, provision, and interpretation of diagnostic testing of individual specimens.

Laboratory testing A process conducted in a clinical laboratory to rule in or rule out a diagnosis, to select and

monitor disease treatment, to provide a prognosis, to screen for a disease, or to determine the severity of and monitor a physiological disturbance.

Molecular diagnostics Use of molecular biology techniques to predict, prevent, diagnose, and monitor disease, including the selection and optimization of therapies.

The disciplines of *clinical chemistry* and *molecular diagnostics* elicit different images. For clinical chemistry, one thinks of pH measurements or large chemistry analyzers, whereas molecular diagnostics conjures up the human genome project, companion diagnostics, and personalized and precision medicine. Although clinical chemistry is at the core of laboratory medicine, molecular diagnostics is a more recent but explosive upstart. Clinical chemistry excels in random access testing, but molecular diagnostics has evolved massively parallel methods. On the surface, these disciplines appear clearly different.

However, consider the meaning behind the words that compose “clinical chemistry” and “molecular diagnostics.” Chemistry by its very nature is molecular, and the study of molecules is chemistry. There is no difference here. Perhaps the “molecular” in “molecular diagnostics” suggests complex polymers with meaningful sequence, excluding simpler chemicals. DNA and RNA sequences largely define life, and powerful technologies for nucleic acids now eclipse those for other complex polymers such as proteins and carbohydrates. In common parlance, molecular diagnostics is dominated by nucleic acids. The words “clinical” and “diagnostics” are also similar, connecting both fields to human disease. “Clinical” is more generic than “diagnostics,” but again in common use, “molecular diagnostics” includes not only diagnostics but prognosis and genetic predisposition as well. In each

*The authors gratefully acknowledge the contributions by David E. Bruns, François A. Rousseau, and Carl A. Burtis on which portions of this chapter are based.

two-word combination, the sum is greater than its parts, with combined meanings evolving to fit needs and interest. We believe that molecular diagnostics is best viewed as a subset of clinical chemistry.

According to the definition of the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC), “Clinical Chemistry is the largest subdiscipline of Laboratory Medicine which is a multidisciplinary medical and scientific specialty with several interacting subdisciplines, such as hematology, immunology, clinical biochemistry, and others. Through these activities clinical chemists influence the practice of medicine for the benefit of the public.”

Clinical laboratories provide *in vitro* testing of chemical, biochemical, and genetic markers in various fluids or tissues of the human body to screen for a disease, confirm or exclude a diagnosis, help to select or monitor a treatment, or assess prognosis. Laboratory testing impacts health care delivery to virtually every patient.

LOOKING BACK

The examination of body fluids for the diagnosis of disease is certainly not a modern concept. The Greeks noticed before 400 BC that ants are attracted to “sweet urine.” However, laboratory testing was not always appreciated by clinicians; the famous Dublin physician Robert James Graves (1796–1853) once remarked, “Few and scanty, indeed, are the rays of light which chemistry has flung on the vital mysteries,” and the pioneer Max Josef von Pettenkofer (1818–1901) stated that clinicians use their chemistry laboratory services only when needed for “luxurious embellishment for a clinical lecture.” Such views have changed throughout the years, and laboratory testing has proven to be a useful tool to clinicians who have grown to depend and rely on laboratory testing in the routine management of their patients [Box 1.1](#).

Although it may be difficult to pinpoint the exact date when the concept of the clinical laboratory was born, all indications point to the mid-19th century. One such indication is an article titled “Hospital Construction” by Francis H. Brown that was published in the *Boston Medical and Surgical Journal*, the precursor of the *New England Journal of Medicine*, in 1861. Dr. Brown stated, “[Every hospital should have] a small

room at the end of the ward to serve as a general laboratory ... necessary small cooking might be accomplished here; dishes and other articles washed, etc.; and it would serve as a general store-room for brooms, pails, and other articles.” Although Baron Justus von Liebig (1803–73) boasted that his clinical laboratory performed more than 400 tests per annum, the average mid- to large-sized laboratory nowadays performs several million tests yearly. The term *clinical chemistry* was purportedly coined by Charles Henry Ralfe (1842–96) of London Hospital when he used it as the title of his 1883 treatise. The first laboratory attached to a hospital was established in 1886 in Munich, Germany, by Hugo Wilhelm von Ziemssen. In the United States the first clinical laboratory was The William Pepper Laboratory of Clinical Medicine, established in 1895 at the University of Pennsylvania in Philadelphia.

Molecular diagnostics has more recent origins. “Molecular diagnosis” was first mentioned in 1968 as the title of a *New England Journal of Medicine* editorial, commenting on a new inborn error of metabolism that overproduced oxalic acid, resulting in kidney stones. “Molecular” referred to an enzymatic pathway and the substrates, not nucleic acid variants. Twenty years later, additional articles describing “molecular diagnostics” began to appear. In 1986, molecular diagnostics was defined as, “... the detection and quantification of specific genes by nucleic acid hybridization procedures,” exemplified by speciation of plant nematodes. In 1987, molecular diagnostics was used to describe mapping of antigenic substances by affinity chromatography using immobilized antibodies. In 1988 the term was used to describe methods for detecting gene amplification and rearrangement using Southern blotting. With the advent of polymerase chain reaction (PCR), the term “molecular diagnostics” became more common, its use doubling in the medical literature every 6 to 7 years. By 1997, commercial real-time PCR instruments solidified “molecular diagnostics” as a branch of clinical chemistry and laboratory medicine.

EXPANDING BOUNDARIES DEFINED BY TECHNOLOGY

Unlike other specialties in laboratory medicine, clinical chemistry is very much influenced and shaped by technology. No discipline in laboratory medicine uses more technologies than clinical chemistry. Technologies that evolved over time not only changed practice but also remodeled the boundaries of the traditional clinical chemistry laboratory. For example, with the emergence of immunochemical techniques in the 1970s, the US Food and Drug Administration approved many tests for the measurement of proteins, small molecule hormones, and drugs, a development that profoundly changed clinical chemistry and its armamentarium of testing. Integrated automated platforms later enabled the measurement of hormones and therapeutic drugs by immunoassays simultaneously with electrolytes, glucose, and other general chemistry tests, thus subsuming the “endocrine lab” and the “drug lab.”

BOX 1.1 Uses of Testing in the Clinical Laboratory

- Confirming a clinical suspicion (which could include making a diagnosis)
- Excluding a diagnosis
- Assisting in selection, optimization, and monitoring of treatment
- Providing a prognosis
- Screening for disease in the absence of clinical signs or symptoms
- Establishing and monitoring the severity of a physiological disturbance

Serologic tests for hepatitis and human immunodeficiency virus (HIV) and tests for autoimmune diseases also moved from their traditional home in microbiology and immunology to chemistry analyzers. Immunoglobulin analysis followed a similar path. The typical clinical chemistry laboratory includes testing for general chemistries, specific proteins and immunoglobulins, therapeutic and abused drugs, blood gases, hormones, biogenic amines, porphyrins, vitamins, and trace elements. Testing for inborn errors of metabolism (such as the measurements of amino acids and organic acids), measurements of coagulation factors, general hematologic testing, and serologic assays can belong either to the clinical chemistry laboratory or to another subspecialty, depending on the institution.

Clinical chemists have embraced technology over the years and used it effectively to derive answers to clinical questions. In modern clinical chemistry laboratories, technologies include spectrophotometry, atomic absorption, flame emission photometry, nephelometry, electrochemical and optical sensor technologies, electrophoresis, and chromatography. The influence of automation, information technology, and miniaturization is evident in current clinical chemistry laboratories. Mass spectrometry, once thought of as a research tool, is playing an ever-growing role in clinical chemistry for the measurement of both small molecules and peptides, and more recently proteins. Point-of-care testing is a disruptive innovation that decentralizes laboratory testing and presents the clinical chemist with many challenges and opportunities.

Molecular diagnostics has forever changed virology and microbiology, introducing faster and more sensitive methods based on nucleic acid amplification rather than microbial replication. Nanotechnology, microfluidics, electrical impedance, reflectance spectroscopy, and time-resolved fluorescence are only a few of the technologies used in point-of-care testing for proteins, drugs, DNA, and analysis of metabolites in small samples of whole blood. Molecular diagnostics in particular impacts diverse specialties, including infectious disease, genetics, and oncology, providing new tools for study at a molecular detail never before considered. In summary, the boundaries of clinical chemistry expand with technology, making the profession vibrant, interesting, and ever evolving.

The scope of the profession is constantly changing for the very same reasons. Scientific and technological developments, medical needs, patient demands, and economic pressures bring various disciplines of medicine closer together, and this integration results in more effective health care. For example, companion diagnostics, which help predict therapeutic responses and individualize patient treatment options, bring together pharmacy and medical laboratories. Point-of-care testing in real time with medical intervention breaks the walls of laboratories to bring the profession closer to clinicians and patients. New disruptive technologies (e.g., “lab on a chip,” nanotechnology, home monitoring) as well as movement toward patient empowerment and direct-to-consumer testing bring laboratory testing closer to patients. All of these developments present special challenges to the future generations of laboratory professionals both in terms of how they should be trained and how they will practice.

Technology alone is not the answer to more effective and cost-effective clinical practice. The laboratory data obtained must be meaningful and support clinical management decisions. The generation of more data does not necessarily lead to better patient management and outcomes. In the 1960s and 1970s, with the advent of automated clinical analyzers, laboratories reported chemistry panels of 10 to 20 results. More recently, dense data from expression arrays, genome-wide association studies, epigenomics, and microRNA analyses excel in discovery research, but translation to clinical practice has been slower than anticipated. The promise of greater clinical significance with larger data sets seems intuitive, but history suggests caution. Clinical chemists in this world of “big data” translate high-quality measurement *data* into clinically relevant *information*. This information—when integrated with clinical history and presentation, clinical signs, and an understanding of pathophysiology—becomes *knowledge*. Knowledge, in the context of the experience and judgment of the clinician, is converted to *wisdom* that translates to clinical action for improved patient outcomes.

HOW IS CLINICAL CHEMISTRY PRACTICED?

Although the majority of clinical chemists choose a career in a clinical laboratory environment, many work in the in vitro diagnostics (IVD) and pharmaceutical industries. Clinical chemists, by virtue of their training, are translational researchers who are capable of developing, evaluating, and validating biochemical and genetic assays for clinical use; they develop skills that are essential for new biomarker assays, reagent kits, and companion diagnostics. Clinical chemists also provide interfaces between researchers, clinicians, the clinical laboratory, and the IVD industry to help translate biomarker research into clinically meaningful decisions and actions.

Clinical chemists practicing in the IVD or the pharmaceutical industry may not need to routinely interact with clinicians or interpret laboratory results, but they understand and appreciate the clinical utility and relevance of the assays and companion diagnostics they are developing and thus contribute more effectively to the development of diagnostics that improve health. The daily practice of the profession has changed over time. In the 1960s and 1970s, clinical chemists developed laboratory tests. At present, *de novo* assay development is still active only in certain areas such as chromatography, mass spectrometry, and molecular diagnostics.

However, as the profession matured and the instrumentation changed from open systems to “black boxes,” the traditional analytical focus of the profession has significantly diminished. Clinical chemists are now more active in the pre-analytical and postanalytical phases of testing and in establishing processes such as how best to select the right test for the right patient and to communicate test results to clinicians in a medically meaningful way, how to build laboratory processes that reduce error, and how to continuously improve the quality of laboratory practices (Box 1.2).

BOX 1.2 Functions of the Laboratory Professional

- Develop and validate de novo laboratory tests to meet clinical needs.
- Evaluate and characterize the analytical and clinical performance of laboratory tests.
- Present laboratory results to clinicians in an effective manner.
- Provide education and advice on the selection and interpretation of laboratory tests as part of the clinical team.
- Determine the cost effectiveness and intrinsic value of laboratory tests.
- Participate in the development of clinical testing algorithms and clinical practice guidelines.
- Ensure compliance with regulatory requirements.
- Participate in quality assurance and improvement of the laboratory service.
- Teach and train future generations of laboratory specialists.
- Participate in basic or clinical research.

In the current health care environment, there is increasing emphasis on clinical impact and cost effectiveness. Laboratories are expected to demonstrate evidence of improved measurable clinical outcomes and the usefulness and added value of tests to clinical decision making. Proving the fact that laboratory testing contributes to improved patient outcomes is challenging because the relationship between testing and clinical outcomes is mostly indirect. Nevertheless, clinical chemists should move away from being just providers of high-quality data. Transforming laboratory data to information and knowledge requires more skills in information and information management technology, evidence-based medicine, epidemiology, data mining, and translational research. It also requires a shift of thinking from essentialism to consequentialism and from technology-driven to customer-focused and patient-centered laboratory medicine.

To summarize, today's clinical chemists are laboratory professionals who are trained in pathophysiology and technology. The execution of their daily duties, which are more clinically or technology oriented, is influenced by their training (such as MD vs. PhD), interests, institutional needs, and the country where they practice. Clearly the practice of our profession has evolved over the past half a century, and there are even more challenges on the horizon that will expand and change its scope and role and enhance its diversity.

GUIDING PRINCIPLES OF PRACTICING THE PROFESSION

As in other branches of medicine, practitioners in the clinical laboratory are faced with ethical issues, often on a daily basis; examples are listed in [Box 1.3](#).

CONFIDENTIALITY OF GENETIC INFORMATION

Confidentiality of genetic information has been prominent in the news in the first and second decades of this millennium.

BOX 1.3 Ethical Issues in Clinical Chemistry and Molecular Diagnostics

- Confidentiality of genetic information
- Confidentiality of patient medical information
- Allocation of resources
- Codes of conduct
- Publishing issues
- Conflicts of interest

Legislation was considered necessary to prevent denial of health insurance or employment to people found by DNA testing to be at risk of disease. Less appreciated is the fact that the issue of confidentiality of clinical laboratory data predated DNA testing. In fact, many non-DNA tests, old and new, also carry information about risks of illness and death. Clinical laboratory professionals have long been responsible for maintaining the confidentiality of all laboratory results, a situation made even more critical with the advent of increasingly powerful genetic testing.

CONFIDENTIALITY OF PATIENT MEDICAL INFORMATION

New test development requires the use of patient samples and may involve the use of patient medical information. Ethical judgments are required regarding the type of informed consent that is needed from patients for use of their samples and clinical information. Clinical laboratory physicians and scientists often serve on institutional review boards that examine proposed research on human subjects. In these discussions, ethical concepts such as clinical equipoise—which refers to the genuine uncertainty in the expert medical community over whether a particular treatment will be beneficial—and confidentiality are central to decisions.

ALLOCATION OF RESOURCES

Because resources are finite, laboratory professionals must make ethically responsible decisions about allocation of resources. There is often a trade-off between cost and quality. What is best for patients generally? How can the most good be done with the available resources? For laboratorians in business, creative accounting may tarnish the profession if patient care is not kept paramount.

CODES OF CONDUCT

Most professional organizations publish a code of conduct that requires adherence by their members. For example, the American Association for Clinical Chemistry (AACC) has published ethical guidelines that require AACC members to endorse principles of ethical conduct in their professional activities, including (1) selection and performance of clinical procedures, (2) research and development, (3) teaching, (4) management, (5) administration, and (6) other forms of professional service.

PUBLISHING ISSUES

Publication of documents having high scientific integrity depends on editors, authors, and reviewers all working in concert in an environment governed by high ethical standards.

Editors are responsible for the overall process, including identifying reviewers, evaluating the reviews and the authors' response to them, and making the final decision of whether to accept or reject a manuscript. Editors are also responsible for establishing policies and procedures to ensure consistency in the editorial process. Finally, the editor-in-chief is responsible for developing a conflict of interest policy and monitoring it among his or her editors. Publishers, being commercial or scientific societies, should monitor any conflicts of interest of the editor-in-chief.

Authors are responsible for honest and complete reporting of original data produced in ethically conducted research studies. Practices such as fraud, plagiarism (verbatim, mosaic), and falsification or fabrication of data are unacceptable. The International Committee of Medical Journal Editors and the Committee on Publication Ethics have published policies that address such behavior. Other practices to be avoided include duplicate publication, redundant publication, and inappropriate authorship credit. In addition, ethical policies require that factors that might influence the interpretation of study findings must be revealed, such as (1) the role of the commercial sponsor in the design and conduct of the study, (2) interpretation of results, and (3) preparation of the manuscript. Additional undesirable and harmful practices are publication bias and selective reporting, in which only studies with positive findings are reported and authors use "data dredging" and meaningless subanalyses to find a positive association rather than reporting the original hypothesis that was negative. These practices inflate the actual value of observations or utility of markers and diminish the quality of meta-analyses. As a result, a comprehensive registry of diagnostic and prognostic studies, similar to the registry of clinical trials, has been advocated.

Reviewers must provide a timely, fair, and impartial assessment of manuscripts. They must maintain confidentiality and never contact the authors until after the publication of the report. Finally, reviewers must excuse themselves from the review process if they perceive a conflict of interest.

Most journals now require authors to complete conflict of interest forms and delineate each author's contribution. Some journals, including *Clinical Chemistry*, publish this information along with the article for enhanced transparency.

CONFLICTS OF INTEREST

The interrelationships between practitioners in the medical field and commercial suppliers of drugs, devices, and equipment can be positive or negative. Concerns led the National Institutes of Health in 1995 to require official institutional

review of financial disclosure by researchers and management in situations when disclosure indicates potential or actual conflicts of interest. In 2009 the Institute of Medicine issued a report that questioned inappropriate relationships between pharmaceutical device companies and physicians and other health care professionals. Similarly, the relationship between clinical laboratory professionals and manufacturers and providers of diagnostic equipment and supplies can be scrutinized.

As a consequence of these concerns and as a result of the enactment of various laws designed to prevent fraud, abuse, and waste in Medicare, Medicaid, and other health care reimbursement programs, professional organizations that represent manufacturers of IVD and other device and health care companies have published codes of ethics. For example, the Advanced Medical Technology Association has published a revised code of ethics that became effective on July 1, 2009. Topics discussed in this revised code include gifts and entertainment, consulting arrangements and royalties, reimbursement for testing, and education. Similarly, the European Diagnostic Manufacturers Association has published a code of ethics, including issues of member-sponsored product training and education, support for third-party educational conferences, sales and promotional meetings, consultants, gifts, provision of reimbursements, and donations for charitable and philanthropic purposes. Both documents address demands from regulators while nurturing the unique role that laboratory and other health care professionals play in developing and refining new technology.

WHAT IS IN THIS TEXTBOOK?

In this textbook, we have assembled what is essential to effectively practice clinical chemistry and molecular diagnostics. We begin with introductory chapters that describe the basics of laboratory medicine, including statistics, sample handling, preanalytical processes, reference intervals, and quality control. This is followed by a section on analytical techniques and applications, describing the main methods used in clinical chemistry, including immunoassays, mass spectrometry, and point-of-care testing. Next, all the major analytes are discussed, including enzymes, tumor markers, therapeutic drugs, and toxicology, among many others. This is followed by a section on pathophysiology that covers disease states and malfunction of different organ systems that correlate with abnormal laboratory findings. Finally, our last section is dedicated to molecular diagnostics, perhaps the fastest growing field in clinical chemistry. An appendix tabulates reference intervals for the clinical laboratory. The online version includes clinical cases, podcasts, and biochemical calculations. Our aim is to provide current scientific and practical knowledge to support laboratory professionals with knowledge resources that interface between science and technology on the one hand and the clinician and the patient on the other.

POINTS TO REMEMBER

- Clinical chemistry is the largest subdiscipline of laboratory medicine, and molecular diagnostics is a subset of clinical chemistry.
- Clinical chemistry is a profession that has been shaped and defined by technology.
- The role of clinical chemists evolved over time from analytically and technology focused to customer and patient centered.
- Clinical chemists are translational researchers who convert laboratory data to clinical knowledge.
- Career paths of clinical chemists are heterogeneous and include work in clinical laboratories and in vitro diagnostics and pharmaceutical industries.
- Clinical chemists must adhere to guiding principles of practicing the profession, which include maintaining confidentiality of genetic and medical information, using resources appropriately, abiding by codes of conduct, following ethical publishing rules, and managing and disclosing conflict of interest.

REVIEW QUESTIONS

1. The clinical laboratory discipline that is used most often to assess inherited disease through study of the constitutive genome is:
 - a. transfusion services.
 - b. clinical chemistry.
 - c. molecular diagnostics.
 - d. hematology.
2. When a practitioner in clinical chemistry has an inappropriate personal relationship with a commercial supplier of chemistry analyzers, there may be a potential issue with:
 - a. publication ethics.
 - b. confidentiality.
 - c. selection of treatment.
 - d. conflict of interest.
3. “Molecular testing” involves the clinical analysis of:
 - a. atoms and molecules.
 - b. nucleic acids.
 - c. cellular components of blood.
 - d. the physical structure of compounds.
4. Which one of the following is not considered an ethical issue facing a clinical laboratorian?
 - a. Allocation of resources
 - b. Conflicts of interest
 - c. Discussion of one’s salary
 - d. Maintenance of confidentiality

Analytical and Clinical Evaluation of Methods

Kristian Linnet, Karel G.M. Moons, James C. Boyd

OBJECTIVES

1. Define the following:
 - Analytical measurement range
 - Analytical specificity
 - Bias
 - Coefficient of variation
 - Correlation coefficient
 - Difference curve
 - Error model
 - Frequency distribution
 - Gaussian probability distribution
 - Limit of detection
 - Linearity
 - Mean
 - Median
 - Population
 - Precision
 - Random error
 - Random sample
 - Regression analysis
 - Sample
 - Standard deviation
 - Systematic error
 - Student *t* distribution
 - Trueness
 - Uncertainty
2. List and describe three criteria that must be considerations in laboratory method selection, including the specific parameters involved in each criterion.
3. Compare population and sample mean, population parameter and sample statistic, and population standard deviation and sample standard deviation, including a description of each, symbols used to express these, how they are calculated, and the information they provide.
4. State the connection of the following concepts to analytical methods:
 - Accuracy
 - Analytical sensitivity
 - Analytical specificity
 - Calibration
 - Limit of detection
 - Linearity
 - Precision
 - Repeatability
 - Reproducibility
5. List two common approaches used to objectively analyze data in a methods comparison study.
6. Describe the components of a difference plot, including the plot's use in method comparison and how the plot is interpreted.
7. Discuss assessment of error in an objective analysis of data in method comparison, including how error occurrence relates to an assay's performance characteristics, the difference between random and systematic error, what causes error, and how error is evaluated in a difference plot.
8. For the following types of analyses, list the components of the analysis, its application in method comparison, how it is computed, how outliers affect it, and how the results are interpreted:
 - Deming regression
 - Nonparametric regression
 - Ordinary least-squares regression
 - Regression
9. Describe the calibration hierarchy, including the tracing of values of routine clinical chemistry measurements to a primary reference, how the values are obtained, and the methods involved; draw a calibration hierarchy given a specific analyte.
10. Discuss the concept of uncertainty in relation to clinical laboratory results, including the components of the standard uncertainty formula and two ways in which uncertainty is assessed.
11. Given appropriate values, state the formula and calculate the following:
 - Coefficient of variation
 - Coefficient of variation percent
 - Deming regression
 - Linear regression
 - Population mean
 - Precision analyses
 - Standard deviation
 - Standard uncertainty

- Likelihood ratio
 - Odds ratio
 - Predictive value
 - Prevalence
 - Receiver operating characteristic curve
 - Sensitivity
 - Specificity
 - True/false positive
 - True/false negative
12. State the formulas for and calculate, given appropriate information, the following: sensitivity, specificity, predictive value for positive/negative tests (posterior probabilities), odds ratio, and positive/negative likelihood ratio.
 13. State the relationship between high sensitivity and false negatives; state the relationship between high specificity and false positives.
 14. Compare dichotomous and continuous tests; include definition, sensitivity/specificity, and a clinical example of each type of test.
 15. State how the predictive value of a laboratory test (posterior probability) is affected by prevalence.
 16. Construct and interpret a receiver operating characteristic curve using data from a diagnostic test study.
 17. Describe the added value of combination testing as it is used in the clinical laboratory; include examples, diagnostic usefulness, and associated problems.

KEY WORDS AND DEFINITIONS

Accuracy of analytical method Closeness of agreement of a single measurement with “true value.”

Analyte The substance being analyzed in an analytical procedure.

Analytical measurement range The analyte concentration range over which measurements are within the declared tolerances for imprecision and bias; also referred to as *reportable range*.

Analytical sensitivity The ability of an analytical method to assess small variations in the concentration of analyte.

Analytical specificity The ability of an assay procedure to determine specifically the concentration of the target analyte in the presence of potentially interfering substances or factors in the sample matrix.

Assay comparison Comparison of measurements by two methods that is carried out objectively using statistical procedures and graphics displays.

Bias In an analytical method, the difference between the average value and the true value that is expressed numerically and is inversely related to the trueness.

Calibration In relation to analytical methods, a function that describes the relationship between instrument signal and concentration of analyte.

Coefficient of variation Relative standard deviation.

Commutability The equivalence of the mathematical relationships between the results of different measurement procedures for a reference material and for representative samples from healthy and diseased individuals.

Correlation coefficient Measure of association between two variables.

Deming regression Least-squares regression analysis taking measurement errors in both variables into account.

Difference plot A bias plot that shows the dispersion of observed differences between the measurements of two methods as a function of the average concentration of the measurements; also referred to as a *Bland-Altman plot*.

Error model A model of the error structure.

Frequency distribution A distribution of the frequency (ordinate) as a function of the variable value (abscissa), that is, a histogram of absolute or relative frequencies.

Gaussian probability distribution Bell shaped relative frequency distribution described under basic statistics.

Likelihood ratio The probability of occurrence of a specific test value given that the disease is present divided by the probability of the same test value if the disease was absent.

Linearity Range of values for which there is a linear relationship between concentration and signal.

Limit of detection An assay characteristic defined as the lowest value that significantly exceeds the measurements of a blank sample.

Matrix In relation to analytical methods, human serum that contains analytes.

Mean Arithmetic average of variables. See Basic Statistics.

Median Equal to the 50th percentile of a set of variables. See Basic Statistics.

Negative predictive value The proportion of subjects with a negative test who do not have the disease.

Odds ratio The probability of the presence of a specific disease divided by the probability of its absence.

Ordinary least-squares regression (OLR) analysis A method used to estimate the unknown parameters in a linear regression assessment performed to minimize the sum of squared vertical distances between observed responses and responses predicted by linear approximation.

Population In relation to analytical methods, the complete set of all observations that might occur as the result of performing a particular procedure according to specified conditions.

Positive predictive value The proportion of subjects with a positive test who have the disease.

Precision The closeness of agreement between independent results of measurements obtained under stipulated conditions. Usually expressed as the standard deviation.

Prevalence The frequency of disease in the population examined.

Random error Error that arises from imprecision of measurement of the type that is described by a Gaussian distribution (e.g., caused by pipetting variability, signal variability).

Random sample A random sample from a population is one in which each member has an equal chance of being selected.

Receiver operating characteristic curve A graph of sensitivity versus 1—specificity for all possible cutoff values of a diagnostic test; used to estimate sensitivity and specificity for various decision cutoffs.

Reference measurement procedure A procedure of highest analytical quality that has been shown to yield values having an uncertainty of measurement commensurate with its intended use, especially in assessing the trueness of other measurement procedures for the same quantity and in characterizing reference materials.

Regression analysis A statistical analysis that compares measurement relations between two analytical methods.

Repeatability Closeness of agreement between results of successive measurements carried out under the same conditions (i.e., corresponding to within-run precision).

Reproducibility Closeness of agreement between results of successive measurements carried out under changed conditions (e.g., corresponding to between-runs).

Sample A finite set of variables drawn from an infinite population of variables.

Sensitivity The proportion of subjects with disease who have a positive laboratory test result.

Specificity The proportion of subjects without disease who have a negative laboratory test result.

Standard deviation Square root of sum of squared deviations from the mean divided by number of variables minus one. See under Basic Statistics.

Student *t* distribution Distribution related to the Gaussian distribution given a limited sample size. See under Basic Statistics.

Systematic error Error in measurement that arises from calibration bias or nonspecificity of an assay and, in the course of a number of analyses of the same analyte, remains constant (y-intercept deviation from zero) or varies in a proportional way (slope deviation from unity) based on the analyte concentration.

Traceability In relation to analytical methods, a concept based on a chain of comparisons of measurements that lead to a known reference value done to ensure reasonable agreement between measurements of routine methods.

Trueness A qualitative term that describes the closeness of agreement between the average value obtained from a large series of results of measurements and a true value.

Uncertainty A parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measure; more briefly, uncertainty is a parameter characterizing the range of values within which the value of the quantity being measured is expected to lie.

ASSAY SELECTION OVERVIEW

The introduction of new or revised laboratory tests, markers, or assays is a common occurrence in the clinical laboratory. Test selection and evaluation are key steps in the process of implementing new measurement procedures (Fig. 2.1).

Evaluation of tests, markers, or assays in the clinical laboratory is influenced strongly by guidelines and accreditation or other regulatory standards. The Clinical and Laboratory Standards Institute (CLSI) has published a series of consensus protocols for clinical chemistry laboratories and manufacturers to follow when evaluating methods (<http://www.clsi.org>). The International Organization for Standardization (ISO) has also developed several documents related to method evaluation (ISOs). In addition, meeting laboratory accreditation requirements has become an important aspect in most countries. Abbreviations are listed in Box 2.1.

Analytical Performance Criteria

In evaluation of a laboratory test, (1) trueness (formerly termed accuracy), (2) precision, (3) analytical range, (4) detection limit, and (5) analytical specificity are of prime importance. The sections in this chapter on laboratory test

evaluation and comparison contain detailed outlines of these concepts. Estimated test performance parameters should be related to analytical performance specifications that ensure acceptable clinical use of the test and its results. For more details related to the recommended models for setting analytical performance specifications, readers are referred to Chapters 4 and 7. From a practical point of view, the “ruggedness” of the test in routine use is of importance, and reliable performance, when used by different operators and with different batches of reagents over long time periods, is essential.

BASIC STATISTICS

In this section, fundamental statistical concepts and techniques are introduced in the context of typical analytical investigations. The basic concepts of (1) populations, (2) samples, (3) parameters, (4) statistics, and (5) probability distributions are defined and illustrated. Two important probability distributions—Gaussian and Student *t*—are introduced and discussed.

Frequency Distribution

A graphical device for displaying a large set of laboratory test results is the **frequency distribution**, also called a *histogram*.

Fig. 2.1 A flow diagram that illustrates the process of introducing a new assay into routine use.

BOX 2.1 Abbreviations

CI	Confidence interval
CV	Coefficient of variation (= SD/x , where x is the concentration)
CV%	= $CV \times 100\%$
CV_A	Analytical coefficient of variation
CV_{RB}	Sample-related random bias coefficient of variation
ISO	International Organization for Standardization
OLR	Ordinary least-squares regression analysis
SD	Standard deviation
SEM	Standard error of the mean (= $SD/\sqrt{N}$)
SD_A	Analytical standard deviation
SD_{RB}	Sample-related random bias standard deviation
$\bar{x}_m$	Mean
$\bar{x}_{mw}$	Weighted mean

Fig. 2.2 shows a frequency distribution displaying the results of serum gamma-glutamyltransferase (GGT) measurements of 100 apparently healthy 20- to 29-year-old men. The frequency distribution is constructed by dividing the measurement scale into cells of equal width; counting the number, n_i , of values that fall within each cell; and drawing a rectangle above each cell whose area (and height because the cell widths are all equal) is proportional to n_i . In this example, the selected cells were 5 to 9, 10 to 14, 15 to 19, 20 to 24, 25 to 29, and so on, with 60 to 64 being the last cell (range of values, 5 to 64 U/L). The ordinate axis of the frequency distribution

Fig. 2.2 Frequency distribution of 100 gamma-glutamyltransferase (GGT) values.

gives the number of values falling within each cell. When this number is divided by the total number of values in the data set, the relative frequency in each cell is obtained.

Often, the position of the value for an individual within a distribution of values is useful medically. The *nonparametric* approach can be used to determine directly the *percentile* of a given subject. Having ranked N subjects according to their values, the n -percentile, Perc_n , may be estimated as the value of the $[N(n/100) + 0.5]$ ordered observation. In the case of a non-integer value, interpolation is carried out between neighbor values. The 50th percentile is the median of the distribution.

Population and Sample

It is useful to obtain information and draw conclusions about the characteristics of the test results for one or more target populations. In the GGT example, interest is focused on the location and spread of the population of GGT values for 20- to 29-year-old healthy men. Thus a working definition of a **population** is the complete set of all observations that might occur as a result of performing a particular procedure according to specified conditions.

Most target populations of interest in clinical chemistry are in principle very large (millions of individuals) and so are impossible to study in their entirety. Usually a subgroup of observations is taken from the population as a basis for forming conclusions about population characteristics. The group of observations that has been selected from the population is called a **sample**. For example, the 100 GGT values make up a sample from a respective target population. However, a sample is used to study the characteristics of a population only if it has been properly selected. For instance, if the analyst is interested in the population of GGT values over various lots of materials and some time period, the sample must be selected to be representative of these factors, as well as of age, sex, and health factors of the individuals in the targeted population. Consequently, exact specification of the target population(s) is necessary before a plan for obtaining the sample(s) can be designed. In this chapter, a sample is also used as a specimen, depending on the context.

Probability and Probability Distributions

Consider again the frequency distribution in **Fig. 2.2**. In addition to the general location and spread of the GGT

Fig. 2.3 Population frequency distribution of gamma-glutamyltransferase (GGT) values.

determinations, other useful information can be easily extracted from this frequency distribution. For instance, 96% (96 of 100) of the determinations are less than 55 U/L, and 91% (91 of 100) are greater than or equal to 10 but less than 50 U/L. Because the cell interval is 5 U/L in this example, statements such as these can be made only to the nearest 5 U/L. A larger sample would allow a smaller cell interval and more refined statements. For a sufficiently large sample, the cell interval can be made so small that the frequency distribution can be approximated by a continuous, smooth curve, similar to that shown in Fig. 2.3. In fact, if the sample is large enough, this can be considered a close representation of the “true” target *population frequency distribution*. In general, the functional form of the population frequency distribution curve of a variable x is denoted by $f(x)$.

The population frequency distribution allows us to make probability statements about the GGT of a randomly selected member of the population of healthy 20- to 29-year-old men. For example, the probability $\Pr(x > x_a)$ that the GGT value x of a randomly selected 20- to 29-year-old healthy man is greater than some particular value x_a is equal to the area under the population frequency distribution to the right of x_a . If $x_a = 58$, then from Fig. 2.3, $\Pr(x > 58) = 0.05$. Similarly, the probability $\Pr(x_a < x < x_b)$ that x is greater than x_a but less than x_b is equal to the area under the population frequency distribution between x_a and x_b . For example, if $x_a = 9$ and $x_b = 58$, then from Fig. 2.3, $\Pr(9 < x < 58) = 0.90$. Because the population frequency distribution provides all information related to probabilities of a randomly selected member of the population, it is called the probability distribution of the population. Although the true probability distribution is never exactly known in practice, it can be approximated with a large sample of observations, that is, test results.

Parameters: Descriptive Measures of a Population

Any population of values can be described by measures of its characteristics. A *parameter* is a constant that describes some particular characteristic of a population. Although most populations of interest in analytical work are infinite in size, for the following definitions, the population will be considered to be of finite size N , where N is very large.

One important characteristic of a population is its *central location*. The parameter most commonly used to describe the central location of a population of N values is the *population mean* (μ):

$$\mu = \frac{\sum x_i}{N}$$

An alternative parameter that indicates the central tendency of a population is the **median**, which is defined as the 50th percentile, Perc_{50} .

Another important characteristic is the *dispersion* of values about the population mean. A parameter very useful in describing this dispersion of a population of N values is the *population variance* σ^2 (sigma squared):

$$\sigma^2 = \frac{\sum (x_i - \mu)^2}{N}$$

The *population standard deviation* (SD) σ , the positive square root of the population variance, is a parameter frequently used to describe the population dispersion in the same units (e.g., mg/dL) as the population values. For a Gaussian distribution, 95% of the population of values are located within the mean $\pm 1.96 \sigma$. If a distribution is non-Gaussian (e.g., asymmetric), an alternative measure of dispersion based on the percentiles may be more appropriate, such as the distance between the 25th and 75th percentiles (the interquartile interval).

Statistics: Descriptive Measures of the Sample

As noted earlier, clinical chemists usually have at hand only a sample of observations (i.e., test results) from the overarching targeted population. A *statistic* is a value calculated from the observations in a sample to estimate a particular characteristic of the target population. As introduced earlier, the sample mean x_m is the arithmetical average of a sample, which is an estimate of μ . Likewise, the sample **standard deviation** (SD) is an estimate of σ , and the **coefficient of variation** (CV) is the ratio of the SD to the mean multiplied by 100%. The equations used to calculate x_m , SD, and CV, respectively, are as follows:

$$x_m = \frac{\sum x_i}{N}$$

$$\text{SD} = \sqrt{\frac{\sum (x_i - x_m)^2}{N - 1}} = \sqrt{\frac{\sum x_i^2 - \frac{(\sum x_i)^2}{N}}{N - 1}}$$

$$\text{CV} = \frac{\text{SD}}{x_m} \times 100\%$$

where x_i is an individual measurement and N is the number of sample measurements.

The SD is an estimate of the dispersion of the distribution. In addition, from the SD, an estimate of the uncertainty of x_m can be derived as an estimate of μ (see later discussion).

Random Sampling

A random sample of individuals from a target population is one in which each member of the population has an equal chance of being selected. A **random sample** is one in which each member of the sample can be considered to be a random

Fig. 2.4 The Gaussian probability distribution.

selection from the target population. Although much of statistical analysis and interpretation depends on the assumption of a random sample from some population, actual data collection often does not satisfy this assumption. In particular, for sequentially generated data, it is often true that observations adjacent to each other tend to be more alike than observations separated in time.

Gaussian Probability Distribution

The **Gaussian probability distribution**, illustrated in Fig. 2.4, is of fundamental importance in statistics for several reasons. As mentioned earlier, a particular test result x will not usually be equal to the true value μ of the specimen being measured. Rather, associated with this particular test result x will be a particular measurement error $\varepsilon = x - \mu$, which is the result of many contributing sources of error. Pure measurement errors tend to follow a probability distribution similar to that shown in Fig. 2.4, where the errors are symmetrically distributed, with smaller errors occurring more frequently than larger ones, and with an expected value of 0. This important fact is known as the central limit effect for distribution of errors: if a measurement error ε is the sum of many independent sources of error, such as $\varepsilon_1, \varepsilon_2, \dots, \varepsilon_k$, several of which are major contributors, the probability distribution of the measurement error ε will tend to be Gaussian as the number of sources of error becomes large.

Another reason for the importance of the Gaussian probability distribution is that many statistical procedures are based on the assumption of a Gaussian distribution of values; this approach is commonly referred to as *parametric*. Furthermore, these procedures usually are not seriously invalidated by departures from this assumption. Finally, the magnitude of the uncertainty associated with sample statistics can be ascertained based on the fact that many sample statistics computed from large samples have a Gaussian probability distribution.

The Gaussian probability distribution is completely characterized by its mean μ and its variance σ^2 . The notation $N(\mu, \sigma^2)$ is often used for the distribution of a variable that is Gaussian with mean μ and variance σ^2 . Probability statements

Fig. 2.5 The t distribution for $\nu = 1, 10$, and ∞ .

about a variable x that follows an $N(\mu, \sigma^2)$ distribution are usually made by considering the variable z ,

$$z = \frac{x - \mu}{\sigma}$$

which is called the *standard Gaussian variable*. The variable z has a Gaussian probability distribution with $\mu = 0$ and $\sigma^2 = 1$, that is, z is $N(0, 1)$. The probability that x is within 2σ of μ [i.e., $\Pr(|x - \mu| < 2\sigma) =$] is 0.9544. Most computer spreadsheet programs can calculate probabilities for all values of z .

Student t Probability Distribution

To determine probabilities associated with a Gaussian distribution, it is necessary to know the population SD σ . In actual practice, σ is often unknown, so z cannot be calculated. However, if a random sample can be taken from the Gaussian population, the sample SD can be calculated, by substituting SD for σ , and computing the value t :

$$t = \frac{x - \mu}{\text{SD}}$$

Under these conditions, the variable t has a probability distribution called the **Student t distribution**. The t distribution is a family of distributions depending on the degrees of freedom $\nu (= N - 1)$ for the sample SD. Several t distributions from this family are shown in Fig. 2.5. When the size of the sample and the degrees of freedom for SD are infinite, there is no uncertainty in SD, so the t distribution is identical to the standard Gaussian distribution. However, when the sample size is small, the uncertainty in SD causes the t distribution to have greater dispersion and heavier tails than the standard Gaussian distribution, as illustrated in Fig. 2.5. At sample sizes above 30, the difference between the t distribution and the Gaussian distribution becomes relatively small and can usually be neglected. Most computer spreadsheet programs can calculate probabilities for all values of t , given the degrees of freedom for SD.

The Student t distribution is commonly used in significance tests, such as comparison of sample means, or in testing conducted if a regression slope differs significantly from 1. Descriptions of these tests can be found in statistics textbooks. Another important application is the estimation of confidence intervals (CIs). CIs are intervals that indicate the uncertainty of a given sample estimate. For example, it can be proved that $X_m \pm t_{\alpha/2} (\text{SD}/N^{0.5})$ provides an approximate

2α -CI for the mean. A common value for α is 0.025 or 2.5%, which thus results in a 0.95% or 95% CI. Given sample sizes of 30 or higher, t_{α} is about 2. ($SD/N^{0.5}$) is called the standard error (SE) of the mean. A CI should be interpreted as follows. Suppose a sampling experiment of drawing 30 observations from a Gaussian population of values is repeated 100 times, and in each case, the 95% CI of the mean is calculated as described. Then, in 95% of the drawings, the true mean μ is included in the 95% CI. According to the central limit theorem, distributions of mean values converge toward the Gaussian distribution irrespective of the primary type of distribution of x . This means that the 95% CI is a robust estimate only minimally influenced by deviations from the Gaussian distribution. In the same way, the t -test is robust toward deviations from normality.

Nonparametric Statistics

Distribution-free statistics, often called nonparametric statistics, provides an alternative to parametric statistical procedures that assume data to have Gaussian distributions. For example, distributions of reference values are often skewed and so do not conform to the Gaussian distribution (see Chapter 5 on reference intervals). Formally, to judge whether a distribution is Gaussian or not, a goodness of fit test should be conducted. A commonly used test is the Kolmogorov-Smirnov test, in which the shape of the sample distribution is compared with the shape presumed for a Gaussian distribution. If the difference exceeds a given critical value, the hypothesis of a Gaussian distribution is rejected, and it is then appropriate to apply nonparametric statistics. A special problem is the occurrence of outliers, (i.e., single measurements highly deviating from the remaining measurements). Outliers may rely on biological factors and so be of real significance (e.g., in the context of estimating reference intervals) or they may be related to clerical errors. Special tests exist for handling outliers.

Given that a distribution is non-Gaussian, it is appropriate to apply nonparametric descriptive statistics based on the percentile or quantile concept. The n -percentile, Perc_n , of a sample of N values may be estimated as the value of the $[N(n/100) + 0.5]$ ordered observation. In the case of a noninteger value, interpolation is carried out between neighbor values. The median is the 50th percentile, which is used as a measure of the center of the distribution. For the GGT example, we would order the $N = 100$ values according to size. The median or 50th percentile is then the value of the $[100(50/100) + 0.5 = 50.5]$ ordered observation (the interpolated value between the 50th and 51st ordered values). The 2.5th and 97.5th percentiles are values of the $[100(2.5/100) + 0.5 = 3]$ and $[100(97.5/100) + 0.5 = 98]$ ordered observations, respectively. When a 95% reference interval is estimated, a nonparametric approach is often preferable because many distributions of reference values are asymmetric. Generally, distributions based on the many biological sources of variation are often non-Gaussian compared with distributions of pure measurement errors that usually are Gaussian.

The nonparametric counterpart to the t -test is the Mann-Whitney test, which provides a significance test for the difference between median values of the two groups to be compared, given the same shape of the distributions. When there are more than two groups, the Kruskal-Wallis test can be applied.

Categorical Variables

When dealing with qualitative tests and in the context of evaluating diagnostic testing, categorical variables that only take the value positive or negative come into play. The performance is here given as proportions or percentages, which are proportions multiplied by 100. For example, the diagnostic **sensitivity** of a test is the proportion of diseased subjects who have a positive result. Having tested, for example, 100 patients, 80 might have had a positive test result. The sensitivity then is 0.8% or 80%. Exact estimates of the uncertainty can be derived from the so-called binomial distribution, but for practical purposes, an approximate expression for the 95% CI is usually applied as the estimated proportion $P \pm 2\text{SE}$, where the SE in this context is derived as:

$$\text{SE} = [P(1 - P)/N]^{0.5}$$

where P is here a proportion and not a percentage. In the example, the SE equals 0.0016 and so the 95% CI is 0.77 to 0.83 or 77% to 83%. The applied approximate formula for the SE is regarded as reasonably valid when NP and $N(1 - P)$ both are equal to or higher than 5.

TECHNICAL VALIDITY OF ANALYTICAL ASSAYS

This section defines the basic concepts used in this chapter: (1) **calibration**, (2) trueness and accuracy, (3) precision, (4) linearity, (5) **limit of detection** (LOD), (6) limit of quantification, (7) **specificity**, and (8) others.

Calibration

The calibration function is the relation between instrument signal (y) and concentration of **analyte** (x), that is,

$$y = f(x)$$

The inverse of this function, also called the measuring function, yields the concentration from response:

$$x = f^{-1}(y)$$

This relationship is established by measurement of samples with known quantities of analyte (calibrators). Solutions of pure chemical standards should be distinguished from samples with known quantities of analyte present in the typical **matrix** that is to be measured (e.g., human serum). The first situation applies typically to a reference measurement procedure that is not influenced by matrix effects; the second case corresponds typically to a routine method that often is influenced by matrix components and so preferably is calibrated using the relevant matrix. Calibration functions may be linear or curved and, in

Fig. 2.6 Relation between concentration (x) and signal response (y) for a linear calibration function. The dispersion in signal response (σ_y) is projected onto the x -axis and is called assay imprecision [$\sigma_x (= \sigma_A)$].

the case of immunoassays, may often take a special form (e.g., modeled by the four-parameter logistic curve). An alternative, model-free approach is to estimate a smoothed spline curve, which often is performed for immunoassays. If the assumed calibration function does not correctly reflect the true relationship between instrument response and analyte concentration, a **systematic error** or **bias** is likely to be associated with the analytical method.

The precision of the analytical method depends on the stability of the instrument response for a given quantity of analyte. In principle, a random dispersion of instrument signal (vertical direction) at a given true concentration transforms into dispersion on the measurement scale (horizontal direction), as is shown schematically (Fig. 2.6). If the calibration function is linear and the imprecision of the signal response is the same over the analytical measurement range, the analytical SD (SD_A) of the method tends to be constant over the analytical measurement range (see Fig. 2.6). If the imprecision increases proportionally to the signal response, the analytical SD of the method tends to increase proportionally to the concentration (x), which means that the *relative* imprecision ($CV = SD/x$) may be constant over the analytical measurement range assuming that the intercept of the calibration line is zero.

Trueness and Accuracy

Trueness of measurements is defined as closeness of agreement between the average value obtained from a large series of results of measurements and the true value.

The difference between the average value (strictly, the mathematical expectation) and the true value is the *bias*, which is expressed numerically and so is inversely related to the trueness. *Trueness* in itself is a qualitative term that can be expressed, for example, as low, medium, or high. From a theoretical point of view, the exact true value for a clinical sample is not available; instead, an “accepted reference value” is used, which is the “true” value that can be determined in practice. Trueness can be evaluated by comparison of measurements by the new test and by some preselected reference measurement procedure, both on the same sample or individuals.

TABLE 2.1 Overview of Qualitative Terms and Quantitative Measures Related to Method Performance

Qualitative Concept	Quantitative Measure
<i>Trueness</i>	<i>Bias</i>
Closeness of agreement of mean value with “true value”	A measure of the systematic error
<i>Precision</i>	<i>Imprecision (SD)</i>
Repeatability (within run)	A measure of the
Intermediate precision (long term)	dispersion of random
Reproducibility (interlaboratory)	errors
<i>Accuracy</i>	<i>Error of measurement</i>
Closeness of agreement of a single measurement with “true value”	Comprises both random and systematic influences

SD, Standard deviation.

The ISO has introduced the trueness expression as a replacement for the term *accuracy*, which now has gained a slightly different meaning. **Accuracy** is the closeness of agreement between the result of a measurement and a true concentration of the analyte. Accuracy thus is influenced by both bias and imprecision and in this way reflects the total error. Accuracy, which in itself is a qualitative term, is inversely related to the “uncertainty” of measurement, which can be quantified as described later (Table 2.1).

In relation to trueness, the concepts *recovery*, *drift*, and *carry-over* may also be considered. *Recovery* is the fraction or percentage increase in concentration that is measured in relation to the amount added. Recovery experiments are typically carried out in the field of drug analysis. It is useful to distinguish between *extraction recovery*, which often is interpreted as the fraction of compound that is carried through an extraction process, and the recovery measured by the entire analytical procedure, in which the addition of an internal standard compensates for losses in the extraction procedure. A recovery close to 100% is a prerequisite for a high degree of trueness, but it does not ensure unbiased results because possible nonspecificity against matrix components (e.g., an interfering substance) is not detected in a recovery experiment. *Drift* is caused by instrument or reagent instability over time, so that calibration becomes gradually biased. Assay *carryover* also must be close to zero to ensure unbiased results.

Precision

Precision has been defined as the closeness of agreement between independent results of measurements obtained under stipulated conditions. The degree of precision is usually derived from statistical measures of imprecision, such as SD or CV ($CV = SD/x$, where x is the measurement concentration), which is inversely related to precision. Imprecision of measurements is solely related to the **random error** of measurements and has no relation to the trueness of measurements.

Precision is specified as follows:

Repeatability: **Repeatability** is the closeness of agreement between results of successive measurements carried out under the same conditions (i.e., corresponding to within-run precision).

Reproducibility: **Reproducibility** is the closeness of agreement between results of measurements performed under changed conditions of measurements (e.g., time, operators, calibrators, reagent lots). Two specifications of reproducibility are often used: total or between-run precision in the laboratory, often termed *intermediate precision*, and inter-laboratory precision (e.g., as observed in external quality assessment schemes [EQAS]) (see Table 2.1).

The total SD (σ_T) may be divided into within-run and between-run components using the principle of analysis of variance of components (variance is the squared SD):

$$\sigma_T^2 = \sigma_{\text{Within-run}}^2 + \sigma_{\text{Between-run}}^2$$

It is not always clear in clinical chemistry publications what is meant by “between-run” variation. Some authors use the term to refer to the total variation of an assay, but others apply the term *between-run variance component* as defined earlier.

In laboratory studies of analytical variation, estimates of imprecision are obtained. It is important to have an adequate number so that analytical variation is not underestimated. Commonly, the number 20 is given as a reasonable number of observations (e.g., suggested in the CLSI guideline for manufacturers). To verify method precision by users, it has been recommended to run internal QC samples for 5 consecutive days in 5 replicates.

To estimate both the within-run imprecision and the total imprecision, a common approach is to measure duplicate control samples in a series of runs. Suppose, for example, that a control is measured in duplicate for 20 runs, in which case 20 observations are present with respect to both components. The dispersion of the means (x_m) of the duplicates is given as follows:

$$\sigma_{x_m}^2 = \frac{\sigma_{\text{Within-run}}^2}{2} + \sigma_{\text{Between-run}}^2$$

From the 20 sets of duplicates, the within-run SD can be derived using the following formula:

$$\text{SD}_{\text{Within-run}} = \left[\frac{\sum d_i^2}{(2 \times 20)} \right]^{0.5}$$

where d_i refers to the difference between the i th set of duplicates. When SDs are estimated, the concept degrees of freedom (df) is used. In a simple situation, the number of degrees of freedom equals $N - 1$. For N duplicates, the number of degrees of freedom is $N(2 - 1) = N$. Thus both variance components are derived in this way. The advantage of this approach is that the within-run estimate is based on several runs, so that an average estimate is obtained rather than only an estimate for one particular run if all 20 observations had been obtained in the same run.

Generally, the estimate of the imprecision improves as more observations become available. Exact confidence limits for the SD can be derived from the χ^2 distribution. A graphical display of 95% CIs at various sample sizes is shown in Fig. 2.7. For example, suppose we have estimated the imprecision as an SD of 5.0 on the basis of $N = 20$ observations. From the figure, the 95% CI extends from about 0.75×5.0 to about 1.45×5.0 , i.e., from 3.8 to 7.3.

Fig. 2.7 Relation between factors indicating the 95% confidence intervals (CIs) of standard deviations (SDs) and the sample size. The true SD is 1, and the solid line indicates the mean estimate, which is slightly downward biased at small sample sizes.

Precision often depends on the concentration of analyte being considered. A presentation of precision as a function of analyte concentration is the precision profile, which usually is plotted in terms of the SD or the CV as a function of analyte concentration (Fig. 2.8).

Linearity

Linearity refers to the relationship between measured and expected values over the analytical measurement range. Linearity may be considered in relation to actual or relative analyte concentrations. In the latter case, a dilution series of a sample may be examined. This dilution series examines whether the measured concentration changes as expected according to the proportional relationship between samples introduced by the dilution factor. Dilution is usually carried out with an appropriate sample matrix (e.g., human serum [individual or pooled serum] or a verified sample diluent).

Evaluation of linearity can be performed visually or by statistical tests. When repeated measurements are available at each concentration, the random variation between measurements and the variation around an estimated regression line may be evaluated by an F -test. When significant nonlinearity is found, it may be useful to explore nonlinear alternatives to the linear regression line (i.e., polynomials of higher degrees). Another approach is to assess the residuals of an estimated regression line. An additional consideration for evaluating proportional concentration relationships is whether an estimated regression line passes through zero or not.

Analytical Measurement Range and Limits of Quantification

The **analytical measurement range** (measuring interval, reportable range) is the analyte concentration range over which measurements are within the declared tolerances for imprecision and bias of the method. Taking drug assays as an example, there exist (arbitrary) requirements of a CV% of less than 15% and a bias of less than 15%. The measurement range then extends from the lowest concentration (lower limit of quantification [LLOQ]) to the highest concentration (upper limit of

Fig. 2.8 Relations between analyte concentration and standard deviation (SD)/coefficient of variation (CV). (A) The SD is constant, so that the CV varies inversely with the analyte concentration. (B) The CV is constant because of a proportional relationship between concentration and SD. (C) A mixed situation with constant SD in the low range and a proportional relationship in the rest of the analytical measurement range.

quantification [ULOQ]) for which these performance specifications are fulfilled. The LLOQ is medically important for many analytes, e.g., thyroid-stimulating hormone (TSH), where low TSH results are useful for the diagnosis of hyperthyroidism.

The LOD may be defined as the lowest value that significantly exceeds the measurements of a blank sample. Thus the limit has been estimated on the basis of repeated measurements of a blank sample and has been *reported* as the mean plus 2 or 3 SDs of the blank measurements. In the interval from LOD up to LLOQ, a result should be reported as “detected” but not provided as a quantitative result.

The LLOQ of an assay should not be confused with analytical sensitivity. The **analytical sensitivity** is defined as ability of an analytical method to assess small differences in the concentration of analyte. The analytical sensitivity depends on the precision of the method. The smallest difference that will be statistically significant equals $2 \times \sqrt{2 \times SD_A}$ at a 5% significance level.

Analytical Specificity and Interference

Analytical specificity is the ability of an assay procedure to determine the concentration of the target analyte without influence from potentially interfering substances or factors in the sample matrix (e.g., hyperlipemia, hemolysis, bilirubin, antibodies, other metabolic molecules, degradation products of the analyte, exogenous substances, anticoagulants).

POINTS TO REMEMBER

- Technical validation of analytical methods focuses on (1) calibration, (2) trueness and accuracy, (3) precision, (4) linearity, (5) LOD, (6) limit of quantification, (7) specificity, and (8) others.
- The difference between the average measured value and the true value is the bias, which can be evaluated by comparison of measurements by the new test and by some preselected reference measurement procedure, both on the same sample or individuals.
- The degree of precision is usually expressed on the basis of statistical measures of imprecision, such as SD or CV ($CV = SD/x$, where x is the measurement concentration).
- The measurement range extends from the lowest concentration (LLOQ) to the highest concentration (ULOQ) for which the analytical performance specifications (imprecision, bias) are fulfilled.
- Analytical specificity is the ability of an assay procedure to determine the concentration of the target analyte without influence from potentially interfering substances or factors in the sample matrix.

ASSAY COMPARISON

Comparison of measurements by two assays can be carried out by parallel measurements of a set of patient samples. To prevent artificial matrix-induced differences, fresh patient samples are the optimal material. A nearly even distribution of values over the analytical measurement range is also preferable. In an ordinary laboratory, comparison of two routine assays is the most frequently occurring situation. Less commonly, comparison of a routine assay with a reference measurement procedure is undertaken. When two routine assays are compared, it is not possible to establish that one set of measurements is the correct one. Rather, the question is whether the new assay can replace the existing one without a systematic change in result values. To address this question, a statistical procedure with graphics display should be applied. A difference (bias) plot, which shows differences as a function of the average concentration of measurements (Bland-Altman plot), or a **regression analysis**.

Basic Error Model

The occurrence of measurement errors is related to the performance characteristics of the assay. It is important to distinguish between pure, random measurement errors, which are present in all measurement procedures, and errors related to incorrect calibration and nonspecificity of the assay. Whereas a reference measurement procedure is associated only with pure random error, a routine method, additionally, is likely to have some bias related to errors in calibration and limitations with regard to specificity. Whereas an erroneous calibration function gives rise to a systematic error, nonspecificity gives an error that typically varies from sample to sample. The error related to nonspecificity thus has a random character, but in contrast to the pure measurement error, it cannot be reduced by repeated measurements of a sample. Although errors related to nonspecificity for a group of samples look like random errors, for the individual sample, this type of error is a bias. Because this bias varies from sample to sample, it has been called a *sample-related random bias*. In the following section, the various error components are incorporated into a formal **error model**.

Measured Value, Target Value, Modified Target Value, and True Value

Taking into account that an analytical method measures analyte concentrations with some random measurement error, it is necessary to distinguish between the actual, measured value and the average result obtained if the given sample was measured an infinite number of times. If the assay is a reference assay without bias and nonspecificity, the following simple relationship holds:

$$x_i = X_{\text{True}i} + \varepsilon_i$$

where x_i represents the measured value, $X_{\text{True}i}$ is the average value for an infinite number of measurements, and ε_i is the deviation of the measured value from the average value. If the sample was measured repeatedly, the average of ε_i would be zero and the SD would equal the analytical SD (σ_A) of the reference measurement procedure. Pure, random measurement error will usually be Gaussian distributed.

In the case of a routine assay, the relationship between the measured value for a sample and the true value becomes more complicated:

$$x_i = X_{\text{True}i} + \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

The *Cal-Bias* term (calibration bias) is a systematic error related to the calibration of the method. This systematic error may be a constant for all measurements corresponding to an offset error, or it may be a function of the analyte concentration (e.g., corresponding to a slope deviation in the case of a linear calibration function). The *Random-Bias_i* term is a bias that is specific for a given sample related to nonspecificity of the method. It may arise because of codetermination of substances that vary in concentration from sample to sample. For example, a chromogenic creatinine method code-termines some other components with creatinine in serum.

The final term in the equation above is the random measurement error term, ε_i . If an infinite number of measurements of a specific sample is performed by the routine method, the random measurement error term ε_i would be zero. The calibration and the random-bias, however, would be unchanged. Thus the average value of an infinite number of measurements would equal the sum of the true value and these bias terms. This average value may be regarded as the target value ($X_{\text{Target}i}$) of the given sample for the routine method:

$$X_{\text{Target}i} = X_{\text{True}i} + \text{Cal-Bias} + \text{Random-Bias}_i$$

As mentioned, the calibration bias represents a systematic error component in relation to the true values measured by a reference measurement procedure. In the context of regression analysis, this systematic error corresponds to the intercept and the slope deviation from unity when a routine method is compared with a reference measurement procedure (outlined in detail later). It is convenient to introduce a modified target value expression ($X'_{\text{Target}i}$) for the routine method to delineate this systematic calibration bias, so that:

$$X'_{\text{Target}i} = X_{\text{True}i} + \text{Cal-Bias}$$

Thus, for a set of samples measured by a routine method, the $X_{\text{Target}i}$ values are distributed around the respective $X'_{\text{Target}i}$ values with an SD, which is called σ_{RB} .

If the assay is a reference method without bias and nonspecificity, the target value and the modified target value equal the true value, that is,

$$X_{\text{Target}i} = X'_{\text{Target}i} = X_{\text{True}i}$$

The error model is outlined in Fig. 2.9.

Calibration Bias and Random Bias

For an individual measurement, the total error is the deviation of x_i from the true value, that is,

$$\text{Total error of } x_i = \text{Cal-Bias} + \text{Random-Bias}_i + \varepsilon_i$$

Estimation of the bias terms requires parallel measurements between the method in question and a reference method. With regard to calibration bias, the possibility of lot-to-lot variation in analytical kit sets should be recognized. Lot-to-lot variation shows up as a calibration bias that changes from lot to lot.

The previous exposition defines the total error in broader terms than is often seen. A traditional total error expression is:

$$\text{Total error} = \text{Bias} + 2 \text{SD}_A$$

This is often interpreted as the calibration bias plus 2 SD_A . If a one-sided statistical perspective is taken, the expression is modified to $\text{Bias} + 1.65 \text{SD}_A$, indicating that 5% of results are located outside the limit. Interpreting the bias as identical with the calibration bias may lead to an underestimation of the total error.

Random bias related to sample-specific interferences may take several forms. It may be a regularly occurring additional random error component, perhaps of the same order of

Fig. 2.9 Outline of basic error model for measurements by a routine assay. (A) The distribution of repeated measurements of the *same* sample, representing a normal distribution around the target value ($X_{\text{Target}i}$) (vertical line) of the sample with a dispersion corresponding to the analytical standard deviation, σ_A . (B) Schematic outline of the dispersion of target value deviations from the respective true values for a population of patient samples. A distribution of an arbitrary form is displayed. The standard deviation equals σ_{RB} . The vertical line indicates the mean of the distribution. (C) The distance from zero to the mean of the target value deviations from the true values represents the calibration bias (mean bias = cal-bias) of the assay.

magnitude as the analytical error. In this context, it is natural to quantify the error in the form of an SD or CV. The most straightforward procedure is to carry out a method comparison study based on a set of patient samples in which one of the methods is a reference method, as outlined later. Another form of sample-related random interference is more rarely occurring gross errors, which typically are seen in the context of immunoassays and are related to unexpected antibody interactions. Such an error usually shows up as an outlier in method comparison studies. Outliers should be investigated to identify their cause, which may be an important limitation in using a given assay.

Assay Comparison Data Model

Here we consider the error model described earlier in relation to the method comparison situation. For a given sample measured by two analytical methods, 1 and 2, the following equations apply:

$$x1_i = X1_{\text{Target}i} + \varepsilon1_i = X_{\text{True}i} + \text{Cal-Bias1} + \text{Random-Bias1}_i + \varepsilon1_i$$

$$x2_i = X2_{\text{Target}i} + \varepsilon2_i = X_{\text{True}i} + \text{Cal-Bias2} + \text{Random-Bias2}_i + \varepsilon2_i$$

In the following, some typical situations using this general model are described. First, comparison of a routine assay with

a reference measurement procedure will be treated. Second, comparison of two routine assays is considered.

Assuming that method 1 is a reference method, the bias components disappear by definition, and the following situation can be described:

$$x1_i = X1_{\text{Target}i} + \varepsilon1_i = X_{\text{True}i} + \varepsilon1_i$$

$$x2_i = X2_{\text{Target}i} + \varepsilon2_i = X_{\text{True}i} + \text{Cal-Bias2} + \text{Random-Bias2}_i + \varepsilon2_i$$

The paired differences become

$$(x2_i - x1_i) = \text{Cal-Bias2} + \text{Random-Bias2}_i + (\varepsilon2_i - \varepsilon1_i)$$

We thus have an expression consisting of a systematic error term (calibration bias of method 2) and two random terms. The Random-Bias2 term is distributed around Cal-Bias2 according to an undefined distribution. $(\varepsilon2_i - \varepsilon1_i)$ is a difference between two random measurement errors that are independent and, commonly, Gaussian distributed. However, we remind readers that the SD for analytical methods often depends on the concentration, as mentioned earlier. For analytes with a wide analytical measurement range (e.g., some hormones), both sample-related random interferences and analytical SDs are likely to depend on the measurement concentration, often in a roughly proportional manner. It may then be more useful to evaluate the *relative* differences— $(x2_i - x1_i)/[(x2_i + x1_i)/2]$ —and accordingly express mean and random bias and analytical error as proportions.

In the comparison of two routine methods, the paired differences become

$$\begin{aligned} (x2_i - x1_i) &= (\text{Cal-Bias2} - \text{Cal-Bias1}) \\ &\quad + (\text{Random-Bias2}_i - \text{Random-Bias1}_i) \\ &\quad + (\varepsilon2_i - \varepsilon1_i) \end{aligned}$$

The expression again consists of a constant term, the difference between the two calibration biases, and two random terms. The first random term is a difference between two random-bias components that may or may not be independent. If the two field methods are based on the same measurement principle, the random bias terms are likely to be correlated. For example, two chromogenic methods for creatinine are likely to be subject to interference from the same chromogenic compounds present in a given serum sample. On the other hand, a chromogenic method and an enzymatic creatinine method are subject to different types of interfering compounds, and the random bias terms may be relatively independent. In the $\varepsilon2_i - \varepsilon1_i$ term, the same relationships as described previously are likely to apply. The general form of the expressed differences is the same in the two situations and the same statistical principles apply.

Planning a Method Comparison Study

Several points require attention, including the (1) number of samples necessary, (2) distribution of analyte concentrations (preferably uniform over the analytical measurement range), and (3) representativeness of the samples. To address the

latter point, samples from relevant patient categories should be included, so that possible interference phenomena can be discovered. Practical aspects related to storage and treatment of samples (e.g., container) and possible artifacts induced by storage (e.g., freezing of samples) and addition of anticoagulants should be considered. Comparison of measurements should preferably be undertaken over several days (e.g., at least 5 days) so that the comparison of methods does not become dependent on the performance of the methods in one particular analytical run. The CLSI guideline EP-09-A3, “Method Comparison and Bias Estimation Using Patient Samples,” suggests measurement of 40 samples in duplicate by each method when a new method is introduced in the laboratory as a substitute for an established one. Additionally, 100 samples in duplicate is proposed for a vendor of an analytical test system. The EP15 guideline “User Verification of Manufacturer’s Claims” suggests a more condensed approach based on a bias or **difference plot** for 20 samples.

Difference (Bland-Altman) Plot

The Bland-Altman plot is usually understood as a plot of the differences against the average results of the methods. Thus the difference plot in this version provides information on the relation between differences and concentration, which is useful in evaluating whether problems exist at certain ranges (e.g., in the high range) caused by nonlinearity of one of the methods. It may also be of interest to observe whether differences tend to increase proportionally with the concentration or whether they are independent of concentration.

The basic version of the difference plot requires plotting of the differences against the average of the measurements. Fig. 2.10 shows the plot for the drug assay comparison data. The interval ± 2 SD of the differences is often delineated around the mean difference. To assess whether the bias is significantly different from zero, the SE of the mean difference is estimated as the SD divided by the square root of the number of paired measurements ($SE = SD/N^{0.5}$) and tested against zero by a *t*-test ($t = [\text{Mean} - 0]/SE$).

Nonparametric limits may also be considered. A constant bias over the analytical measurement range changes the average concentration away from zero. The presence of sample-related random interferences increases the width of the distribution. If the calibration bias depends on the concentration, if the dispersion varies with the concentration, or if both occur, the relations become more complex, and the interval mean ± 2 SD of the differences may not fit very well as a 95% interval throughout the analytical measurement range.

The displayed Bland-Altman plot for the drug assay comparison data (see Fig. 2.10) shows a tendency toward increasing scatter with increasing concentration, which is a reflection of increasing random error with concentration. Thus a plot of the relative differences against the average concentration is of relevance (Fig. 2.11).

Regression Analysis

Regression analysis has the advantage that it allows the relation between the target values for the two compared methods

Fig. 2.10 Bland-Altman plot of differences for the drug comparison example. The differences are plotted against the average concentration. The mean difference (42 nmol/L) with ± 2 standard deviation of differences is shown (dashed lines).

Fig. 2.11 Bland-Altman plot of relative differences for the drug comparison example. The differences are plotted against the average concentration. The mean relative difference (0.042) with ± 2 standard deviation of relative differences is shown (dashed lines).

to be studied over the full analytical measurement range. In linear regression analysis, it is assumed that the systematic difference between target values can be modeled as a constant systematic difference (intercept deviation from zero) combined with a proportional systematic difference (slope deviation from unity), usually related to a discrepancy with regard to calibration of the methods. In situations when random errors have a constant SD, unweighted regression procedures are used (e.g., **Deming regression** analysis). For cases with SDs that are proportional to the concentration, the weighted Deming regression procedure is preferred.

As outlined previously, we distinguish between the measured value (x_i) and the target value ($X_{\text{Target}i}$) of a sample subjected to analysis by a given method. In linear regression analysis, we assume a linear relationship between values devoid of random error of any kind. Thus to operate with a

linear relationship between values without random measurement error and sample-related random bias, we have to introduce modified target values:

$$X1_{\text{Target}i} = X1'_{\text{Target}i} + \text{Random-Bias}1_i$$

$$X2_{\text{Target}i} = X2'_{\text{Target}i} + \text{Random-Bias}2_i$$

where we now assume a linear relationship between these modified target values:

$$X2'_{\text{Target}i} = \alpha_0 + \beta X1'_{\text{Target}i}$$

In this model, α_0 corresponds to a constant difference with regard to calibration, and $(\beta - 1)$ is a proportional deviation. Thus the systematic error or calibration difference between the measurements corresponds to

$$X2'_{\text{Target}i} - X1'_{\text{Target}i} = \alpha_0 + (\beta - 1) X1'_{\text{Target}i}$$

Because of sample-related random interferences and measurement imprecision (of the type that can be described by a Gaussian distribution, e.g., caused by pipetting variability, signal variability), individually measured pairs of values ($x1_i$, $x2_i$) will be scattered around the line expressing the relationship between $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$. Fig. 2.12 outlines schematically how the random distribution of $x1$ and $x2$ values occurs around the regression line. We have

$$x1_i = X1_{\text{Target}i} + \varepsilon1_i = X1'_{\text{Target}i} + \text{Random-Bias}1_i + \varepsilon1_i$$

$$x2_i = X2_{\text{Target}i} + \varepsilon2_i = X2'_{\text{Target}i} + \text{Random-Bias}2_i + \varepsilon2_i$$

The random error components may be expressed as SDs, and generally we can assume that sample-related random bias (SD σ_{RB}) and analytical imprecision (SD σ_{A}) are independent for each analyte, yielding the relations

$$\sigma_{\text{ex}1}^2 = \sigma_{\text{RB}1}^2 + \sigma_{\text{A}1}^2$$

$$\sigma_{\text{ex}2}^2 = \sigma_{\text{RB}2}^2 + \sigma_{\text{A}2}^2$$

$\sigma_{\text{ex}1}$ and $\sigma_{\text{ex}2}$ are the total SDs of the distributions of $x1_i$ and $x2_i$ around their respective modified target values, $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$. The sample-related random bias components for methods 1 and 2 may not necessarily be independent. They also may not be Gaussian distributed, contrary to the analytical components. Thus, when a regression procedure is applied, the explicit assumptions to take into account should be considered. In situations without random bias components of any significance, the relationships simplify to

$$\sigma_{\text{ex}1}^2 = \sigma_{\text{A}1}^2$$

$$\sigma_{\text{ex}2}^2 = \sigma_{\text{A}2}^2$$

In this situation, it usually can be assumed that the error distributions are Gaussian, and estimates of the analytical SDs may be available from QC data.

Fig. 2.12 Outline of the relation between $x1$ and $x2$ values measured by two assays subject to random errors with constant standard deviations over the analytical measurement range. A linear relationship between the modified target values ($X1'_{\text{Target}i}$, $X2'_{\text{Target}i}$) is presumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$, respectively, as schematically shown. σ_{21} (σ_{yx}) is demarcated.

Fig. 2.13 Outline of the relation between $x1$ and $x2$ values measured by two assays subject to proportional random errors. A linear relationship between the modified target values is assumed. The $x1_i$ and $x2_i$ values are Gaussian distributed around $X1'_{\text{Target}i}$ and $X2'_{\text{Target}i}$, respectively, with increasing scatter at higher concentrations, as is shown schematically.

Another methodologic problem concerns the question of whether the dispersion of sample-related random bias and the analytical imprecision are constant or change with the analyte concentration. In cases with a considerable range (i.e., a decade or longer), this phenomenon should also be taken into account when a regression analysis is applied. Fig. 2.13 schematically shows how dispersions may increase proportionally with concentration.

Deming Regression Analysis and Ordinary Least-Squares Regression Analysis (Constant Standard Deviations)

To reliably estimate the relationship between modified target values (i.e., a_0 for α_0 and b for β), a regression procedure taking into account errors in both $x1$ and $x2$ is preferable (i.e., Deming approach) (see Fig. 2.12). Although the ordinary

Fig. 2.14 The model assumed in ordinary least-squares regression. The x_2 values are Gaussian distributed around the line with constant standard deviation over the analytical measurement range. The x_1 values are assumed to be without random error. σ_{21} (σ_{yx}) is shown.

least-squares regression (OLR) procedure is commonly used in method comparison studies, it does not take errors in x_1 into account but is based on the assumption that only the x_2 measurements are subject to random errors (Fig. 2.14). In the Deming procedure, the sum of squared distances from measured sets of values (x_{1i}, x_{2i}) to the regression line is minimized at an angle determined by the ratio between SDs for the random variations of x_1 and x_2 . It can be proven theoretically that, given Gaussian error distributions, this estimation procedure is optimal. It should here be noted that it is the error distributions that should be Gaussian, not the dispersion of values over the measurement range. In Fig. 2.15, the symmetric case is illustrated with a regression slope of 1 and equal SDs for the random variations of x_1 and x_2 , in which case the sum of squared distances is minimized orthogonally in relation to the line.

OLR regression is not recommended except in special situations. In OLR, the sum of squared distances is minimized in the vertical direction to the line (see Fig. 2.15). The neglect of the random error in x_1 induces a downward biased slope estimate, which depends on the ratio between the SD for the random error in x_1 and the SD of the X_1 ' target values. Fig. 2.16 shows the bias as a function of the ratio of the random error SD to the SD of the X_1 ' target value dispersion. For a ratio up to 0.1, the bias is less than 1%. At a ratio of 0.33, the bias amounts to 10%. In a given case, the analytical SD (e.g., from QC data) can be divided by the SD of the measured x_1 values, which approximately equals the SD of X_1 ' target values. As an example, a typical comparison study for two serum sodium methods may be associated with a downward directed slope bias of about 10% (Fig. 2.17).

Computation Procedures for Ordinary Least-Squares Regression and Deming Regression

Assuming no errors in x_1 and a Gaussian error distribution of x_2 with constant SD throughout the analytical measurement range, OLR is the optimal estimation procedure. Given errors in both x_1 and x_2 , the Deming approach is

Fig. 2.15 In ordinary least-squares regression (OLR), the sum of squared deviations from the line is minimized in the vertical direction. In Deming regression analysis, the sum of squared deviations is minimized at an angle to the line, depending on the random error ratio. Here the symmetric case is displayed with orthogonal deviations. (From Linnet, K. [1998]. The performance of Deming regression analysis in case of a misspecified analytical error ratio. *Clinical Chemistry*, 44, 1024–1031.)

Fig. 2.16 Relations between the true (expected) slope value and the average estimated slope by ordinary least-squares regression (OLR). The bias of the OLR slope estimate increases negatively for increasing ratios of the standard deviation (SD) random error in x_1 to the SD of the X_1 target value distribution.

the method of choice. It should be noted for these parametric procedures that only the error distributions must be Gaussian or normal to ensure the nominal type I errors for associated statistical tests for slope and intercept hold true. The procedures are generally robust toward deviations from normality, but they are sensitive to outliers because of the squaring principle. Finally, the distribution of the x_1 and x_2 values over the measurement range does not have to be normal. A uniform distribution over the analytical

Fig. 2.17 Simulated comparison of two sodium methods. The *solid line* indicates the average estimated ordinary least-squares regression (OLR) line, and the *dotted line* is the identity line. Even though no systematic difference is evident between the two methods, the average OLR line deviates from the identity line corresponding to a downward slope bias of about 10%.

measurement range is generally of advantage, but the distribution in principle may take any form. For both procedures, we may evaluate the SD of the dispersion in the *vertical* direction around the line (commonly denoted $SD_{y,x}$ and here given as SD_{21}). We have

$$SD_{21} = \left[\sum (x_{2i} - \bar{x}_{2\text{Targettesti}})^2 / (N - 2) \right]^{0.5}$$

Further discussion regarding the interpretation of SD_{21} will be given later.

To compute the slope in Deming regression analysis, the ratio between the SDs of the random errors of x_1 and x_2 is necessary, that is,

$$\lambda = (\sigma_{RB1}^2 + \sigma_{A1}^2) / (\sigma_{RB2}^2 + \sigma_{A2}^2)$$

SD_{AS} can be estimated from duplicate sets of measurements as

$$SD_{A1}^2 = (1/2M) \left[\sum (x_{12i} - x_{11i})^2 \right]$$

$$SD_{A2}^2 = (1/2M) \left[\sum (x_{22i} - x_{21i})^2 \right]$$

If a specific value for λ is not available and the two routine methods that are compared are likely to be associated with random errors of the same order of magnitude, λ can be set to 1. The Deming procedure is generally relatively insensitive to a misspecification of the λ value.

Formulas for computing slope (β), intercept (α_0), and their SEs are available from other sources and are not provided here.

Evaluation of the Random Error Around an Estimated Regression Line

The estimated slope and intercept provide an estimate of the systematic difference or calibration bias between two

methods over the analytical measurement range. An estimate of the random error is the dispersion around the line in the vertical direction, which is quantified as $SD_{y,x}$ (here denoted SD_{21}). We have here without sample-related random interferences

$$\sigma_{21}^2 = \beta^2 \sigma_{A1}^2 + \sigma_{A2}^2$$

Thus σ_{21} reflects the random error both in x_1 (with a rescaling) and in x_2 . Often β is close to unity, and in this case, σ_{21}^2 becomes approximately the sum of the individual squared SDs. This relation holds true for both Deming and OLR analyses. Frequently, OLR is applied in situations associated with random measurement error in both x_1 and x_2 , and in these situations, σ_{21} reflects the errors in both.

The presence of sample-related random interferences in both x_1 and x_2 gives the following expression:

$$\sigma_{21}^2 = (\beta^2 \sigma_{A1}^2 + \sigma_{A2}^2) + (\beta^2 \sigma_{RB1}^2 + \sigma_{RB2}^2)$$

Thus the σ_{21} value is influenced by the slope value and the analytical error components σ_{A1} and σ_{A2} (grouped in the first bracket) and σ_{RB1} and σ_{RB2} (grouped in the second bracket). In many cases, the slope is close to unity, in which case we have simple addition of the components. Information on the analytical components is usually available from duplicate sets of measurements or from QC data. On this basis, the combined random bias term in the second bracket can be derived by subtracting the analytical components from σ_{21} . Overall, it can be judged whether the total random error is acceptable or not. The systematic difference can be adjusted for relatively easily by rescaling one of the sets of measurements. However, if the random error term is very large, such a rescaling does not ensure equivalency of measurements with regard to individual samples.

Assessment of Outliers

The distance from a suspected outlier to the line is recorded in SD units, and the outlier is rejected if the distance exceeds a predetermined limit (e.g., 3 or 4 SD units). In the case of OLR, the SD unit equals SD_{21} , and the vertical distance is considered. For Deming regression analysis, the unit is the SD of the deviation of the points from the line at an angle determined by the error variance ratio λ . A plot of these deviations, a so-called residuals plot, conveniently illustrates the occurrence of outliers. Fig. 2.18A illustrates an example of Deming regression analysis with occurrence of an outlier and the associated residuals plot (see Fig. 2.18B), which clearly shows the outlier pattern. In this example, the residuals plot was standardized to unit SD. Use of an outlier limit of 4 SD units in this example led to rejection of the outlier, and a reanalysis was undertaken. In this example, rejection of the outlier changed the slope from 1.14 to 1.03. With regard to outliers, the reason for their presence should be investigated as a method limitation (e.g., possibly a nonspecificity for the analyte).

Fig. 2.18 (A) A scatter plot with the Deming regression line (solid line) with an outlier (filled point). The dotted straight line is the diagonal, and the curved dashed lines demarcate the 95% confidence region. (B) Standardized residuals plot with indication of the outlier.

Correlation Coefficient

The ordinary **correlation coefficient**, ρ , also called the Pearson product moment correlation coefficient, is estimated as r from sums of squared deviations for x_1 and x_2 values as follows:

$$r = \rho / (uq)^{0.5}$$

where

$$p = \sum (x_{1i} - x_{1m})(x_{2i} - x_{2m})$$

$$u = \sum (x_{1i} - x_{1m})^2 \text{ and } q = \sum (x_{2i} - x_{2m})^2$$

and

$$x_{1m} = \sum x_{1i} / N \text{ and } x_{2m} = \sum x_{2i} / N$$

The correlation coefficient r is a *relative* indicator of the amount of dispersion around the regression line. If the numeric interval of values is short, r tends to be low and vice versa for a long range of values. For example, consider simulated examples, where the random errors of x_1 and x_2 are the same but the width of the distributions of measured values differs (Fig. 2.19A and B). In A, the target values are uniformly distributed over the range 1 to 3, and in B, the range is 1 to 6. The random error SD is presumed constant, and it is set to 0.15 for both x_1 and x_2 , corresponding to a CV of 5% at the value 3. Given sets of 50 paired measurements, the correlation coefficient is 0.93 in case A and 0.99 in case B. Furthermore, a single point located outside the range of the rest of the observations exerts a strong influence, resulting in a value of 0.97 (see Fig. 2.19C).

Although σ_{21} is the relevant measure for random error in method comparison studies, ρ is still incorrectly used as a supposed measure of agreement between two methods. A systematic difference due to a difference with regard to calibration is not expressed through ρ but solely in the form of an intercept (α_0) deviation from zero or a slope (β) deviation from unity.

Regression Analysis in Cases of Proportional Random Error

For analytes with extended ranges (e.g., 1 or several decades), the SD_A is seldom constant. Rather, a proportional relationship may apply. This may also be true for the random bias components. In this situation, the regression procedures described previously may still be used, but they are not optimal because the SEs of slope and intercept become larger than is the case when a weighted form of regression analysis is applied. Given a proportional relationship, a weighted procedure assigns larger weights to observations in the low range; low-range observations are more precise than measurements at higher concentrations that are subject to larger random errors. More specifically, weights are applied in the computations that are inversely proportional to the squared SDs (variances) that express the random error. In the weighted modification of the Deming procedure, distances from (x_{1i}, x_{2i}) to the line are inversely weighted according to the squared SDs at a given concentration (Fig. 2.20).

Testing for Linearity

Splitting of the systematic error into a constant and a proportional component depends on the assumption of linearity. A convenient test is a runs test, which in principle assesses whether negative and positive deviations from the points to the line are randomly distributed. The term *run* here relates to a sequence of deviations with the same sign. Consider, for example, the situation with a downward trend of x_2 values at the upper end of the analytical measurement range (Fig. 2.21A). The SDs from the line (i.e.,

Fig. 2.19 Scatter plots illustrating the effect of the range on the value of the correlation coefficient ρ . (A) Target values are uniformly distributed over the range 1 to 3 with random errors of both x_1 and x_2 corresponding to a standard deviation (SD) of 5% of the target value at 3 (constant error SDs). (B) The range is extended to 1 to 6 with the same random error levels. The correlation coefficient equals 0.93 in A and 0.99 in B. (C) The effect of a single aberrant point is shown. Forty-nine of the target values are distributed over the range 1 to 3, with a single point at 6. The correlation coefficient is 0.97.

Fig. 2.20 Distances from data points to the line in weighted Deming regression assuming proportional random errors in x_1 and x_2 . The symmetric case is illustrated with equal random errors and a slope of unity yielding orthogonal projections onto the line. (Modified from Linnet, K. [1999]. Necessary sample size for method comparison studies based on regression analysis. *Clinical Chemistry*, 45, 882–894. Used with permission.)

Fig. 2.21 (A) Scatter plot showing an example of nonlinearity in the form of downward-deviating x_2 values at the upper part of the range. (B) Plot of residuals showing the effects of nonlinearity. At the upper end of the analytical measurement range, a sequence (run) of negative residuals is present.

the residuals) will tend to be negative in this area instead of being randomly distributed above and below the line (see Fig. 2.21B).

Nonparametric Regression Analysis (Passing-Bablok Procedure)

The slope and the intercept may be estimated by a nonparametric procedure, which is robust to outliers and requires no assumptions of Gaussian error distributions. The method takes measurement errors for both x_1 and x_2 into account, but it presumes that the ratio between random errors is related to the slope in a fixed manner:

$$\lambda = (SD_{RB1}^2 + SD_{A1}^2) / (SD_{RB2}^2 + SD_{A2}^2) = 1/\beta^2$$

Otherwise, a biased slope estimate is obtained. The procedure may be applied both in situations with random errors with constant SDs and in cases with proportional SDs. The method is not as efficient as the corresponding parametric procedures. Slope and intercept with CIs are provided, together with Spearman's rank correlation coefficient.

Interpretation of Systematic Differences Between Methods Obtained on the Basis of Regression Analysis

A systematic difference between two methods is identified if the estimated intercept differs significantly from zero or if the slope deviates significantly from 1. This is decided on the basis of t -tests:

$$t = (a_0 - 0) / SE(a_0)$$

$$t = (b - 1) / SE(b)$$

The t -tests can be supplemented with 95% CIs.

$SE(a_0)$ and $SE(b)$ are the SEs of the estimated intercept a_0 and the slope b , respectively. SEs can be derived by a computerized resampling principle called *the jackknife procedure*, which in practice can be carried out using appropriate software. Having estimated a_0 and b , we have the estimate of the systematic difference between the methods, D_c , at a selected concentration, $X1'_{Targetc}$:

$$D_c = X2'_{Targetc} - X1'_{Targetc} = a_0 + (b - 1) X1'_{Targetc}$$

$X2'_{Targetc}$ is the estimated $X2'$ target value at $X1'_c$. Note that D_c refers to the *systematic difference* (i.e., the difference between modified target values corresponding to a calibration difference). The SE of D_c can be derived by the jackknife procedure using a software program. By evaluating the SE throughout the analytical measurement range, a confidence region for the estimated line can be displayed. If method comparison is performed to assess the calibration to a reference measurement procedure, correction of a significant systematic difference Δ_{c} will often be performed by recalibration [$x2_{rec} = (x1 - a_0)/b$]. The associated standard uncertainty is the SE of Δ_{c} .

Fig. 2.22 An example of weighted Deming regression analysis for the comparison of drug assays. (A) The solid line is the estimated weighted Deming regression line, the dashed curves indicate the 95% confidence region, and the dotted line is the line of identity. (B) A plot of residuals standardized to unit standard deviation. The homogeneous scatter supports the assumed proportional error model and the assumption of linearity.

Example of Application of Regression Analysis (Weighted Deming Analysis)

Application of weighted Deming regression analysis may be illustrated by the comparison of drug assays example [$N = 65$ (x_1, x_2) single measurements]. As outlined in the section on the Bland-Altman plot (see Fig. 2.10), in this example the random error of the differences increases with the concentration, suggesting that the weighted form of Deming regression analysis is appropriate. Fig. 2.22 shows (A) the estimated regression line with 95% confidence bands and (B) a plot of normalized residuals. The nearly homogeneous scatter in the residuals plot supports the assumed proportional random error model and the assumption of linearity. The slope estimate (1.014) is not significantly different from 1 (95% CI: 0.97 to 1.06), and the intercept is not significantly different from zero (95% CI: -6.7 to 47.4) (Table 2.2). A runs test for linearity does not contradict the assumption of linearity. The amount of random error is quantified in the form

TABLE 2.2 Results of Weighted Deming Regression Analysis for the Comparison of Drug Assays Example, $n = 65$ Single (x_1, x_2) Measurements

	Estimate	SE	95% CI
Slope (b)	1.014	0.022	0.97–1.06
Intercept (a_0)	20.3	13.5	–6.7 to 47.4
Weighted correlation coefficient	0.98		
SD ₂₁ proportionality factor	0.11		
Runs test for linearity	NS		
$\Delta_{\text{low}} = X_2 - X_1$ at $X_c = 300$	24.6	9.5	5.72–43.6
$\Delta_{\text{high}} = X_2 - X_1$ at $X_c = 2000$	48.9	34.2	–19.3 to 117

CI, Confidence interval; NS, not significant; SD, standard deviation; SE, standard error.

of the SD₂₁ proportionality factor equal to 0.11, or 11%. In the present example, with a slope close to unity and two routine methods with assumed random errors of about the same magnitude, we divide the random error by the square root of 2 and get $CV_{x1} = CV_{x2} = 7.8\%$. QC data in the laboratory have provided CV_{As} of 6.1% and 7.2% for methods 1 and 2, respectively. Thus in this example, the random error may be attributed largely to analytical error. The assay principle for both methods is high performance liquid chromatography (HPLC), which generally is a rather specific measurement principle; considerable random bias effects are not expected in this case.

In Table 2.2, estimated systematic differences at the limits of the therapeutic interval (300 and 2000 nmol/L) are displayed (24.6 and 48.9 nmol/L, respectively). This corresponds to percentage values of 8.2% and 2.4%, respectively. Estimated SEs by the jackknife procedure yield the 95% CIs, as shown in the table. At the low concentration, the difference is significant (95% CI: 5.7 to 44 nmol/L; does not include zero), which is not the case at the high level (95% CI: –19 to 117 nmol/L). Even though the intercept and slope estimates separately are not significantly different from the null hypothesis values of 0 and 1, respectively, the combined difference Δ_{low} is significant at low concentrations in this example. If the difference is considered of medical importance and both methods are to be used simultaneously in the laboratory, recalibration of one of the methods might be considered.

MONITORING SERIAL RESULTS

An important aspect of clinical chemistry is monitoring of disease or treatment (e.g., tumor markers in cases of cancer, drug concentrations in cases of therapeutic drug monitoring). To assess changes in a rational way, various imprecision components have to be taken into account. Biologic within-subject variation (SD_I) and preanalytical (SD_{PA}) and analytical variation (SD_A) all have to be recognized. Assuming that preanalytical variation is already included in the estimated

Fig. 2.23 The calibration hierarchy from a reference measurement procedure to a routine assay. The uncertainty increases from top to bottom. Cal., Calibration.

within-subject variation SD, a total SD (SD_T) can be estimated as follows:

$$SD_T^2 = SD_{\text{WithinB}}^2 + SD_A^2$$

The limit for statistically significant changes then is $[fx2]$, where k depends on the desired probability level. Considering a two-sided 5% level, k is 1.96. The corresponding one-sided factor is 1.65. If a higher probability level is desired, k should be increased.

TRACEABILITY

To ensure reasonable agreement between measurements of routine methods, the concept of traceability comes into focus. (See also Chapter 7 for further detail.) **Traceability** is based on an unbroken chain of comparisons of measurements leading to a known reference value (Fig. 2.23). For well-established analytes, a hierarchy of methods exists with a *reference measurement procedure* at the top, *selected measurement procedures* at an intermediate level, and finally *routine measurement procedures* at the bottom. A **reference measurement procedure** is a fully understood procedure of highest analytical quality containing a complete uncertainty budget given in *Système Internationale* (SI) units. Reference procedures are used to measure the analyte concentration in *secondary reference materials*, which typically have the same matrix as samples that are to be measured by routine procedures (e.g., human serum). Secondary reference materials are usually of high

analytical quality, and certified secondary reference materials must be validated for **commutability** with clinical samples if they are intended for use as trueness controls for routine methods. Otherwise, their use is restricted to selected measurement procedures for which they are intended. The certificate of analysis should state the methods for which the secondary reference materials have been validated to be commutable with clinical samples. When no information is given for commutability, it must be assumed that the reference material is not commutable with clinical samples, and the user has the responsibility to validate commutability for the methods of interest.

Using cortisol as an example, the primary reference material is crystalline cortisol with a chemical analysis for impurities (National Institute of Standards and Technology [NIST] standard reference material 921, cortisol [hydrocortisone]). A primary calibrator is then a cortisol preparation with a stated mass fraction (purity) (e.g., 0.998 and a 95% CI of ± 0.001). The reference measurement procedure is an isotope-dilution gas chromatography–mass spectrometry method that is calibrated with the primary calibrator. A panel of individual frozen serum samples that have values assigned by the primary reference measurement procedure is available from the Institute for Reference Materials and Measurements (IRMM) as secondary reference materials (European Reference Material [ERM]-DA451/International Federation of Clinical Chemistry and Laboratory Medicine [IFCC]). A manufacturer's *selected measurement* procedure is calibrated with the secondary reference materials and is used for measurement of the quantity in the manufacturer's *product calibrator*, which is the calibrator used for the routine method in clinical laboratories.

In case a reference measurement procedure exists for an analyte (measurand), comparable results among measurement procedures can be achieved as described earlier, so-called standardization. When reference measurement procedures are not available, so-called harmonization refers to the process of establishing comparable results among measurement procedures for the given analyte. Harmonization is typically based on distribution among laboratories of commutable secondary reference materials with arbitrarily set target values (see Chapter 7).

Uncertainty Concept

According to the ISO's "Guide to the Expression of Uncertainty in Measurement" (GUM), **uncertainty** is formally defined as "a parameter associated with the result of a measurement that characterizes the dispersion of the values that could reasonably be attributed to the measurand." In practice, this means that the uncertainty is given as an interval around a reported laboratory result that specifies the location of the true value with a given probability (e.g., 95%). In general, the uncertainty of a result, which is traceable to a particular reference, is the uncertainty of that reference together with the overall uncertainty of the traceability chain.

In the outline of the uncertainty concept, it is assumed that any known systematic error components of a measurement

method have been corrected, and the specified uncertainty includes uncertainty associated with correction of the systematic error(s). A distinction between type A and B uncertainties is made. Type A uncertainties are frequency-based estimates of SDs (e.g., an SD of the imprecision). Type B uncertainties are uncertainty components for which frequency-based SDs are not available. Instead, uncertainty is estimated by other approaches or by the opinion of experts. Finally, the total uncertainty is derived from a combination of all sources of uncertainty and can be expressed as a *standard uncertainty* (u_{st}), which is equivalent to an SD. By multiplication of a standard uncertainty with a *coverage factor* (k), the uncertainty corresponding to a specified probability level is derived, e.g. multiplication with a coverage factor of 2 yields a probability level of $\approx 95\%$, given a Gaussian distribution. When the total uncertainty of an analytical result obtained by a routine method is considered (u_{st}), preanalytical variation (u_{PAst}), method imprecision (u_{Ast}), sample-related random interferences (u_{RBst}), and uncertainty related to calibration and bias corrections (traceability) (u_{Tracst}) should be taken into account. In expressing the uncertainty components as standard uncertainties, we have:

$$u_{st} = [u_{PAst}^2 + u_{Ast}^2 + u_{RBst}^2 + u_{Tracst}^2]^{0.5}$$

In principle, uncertainty can be judged *directly* from measurement comparisons ("top down") or *indirectly* from an analysis of individual error sources according to the law of error propagation ("error budget," "bottom up").

Example of Direct Assessment of Uncertainty on the Basis of Measurements of a Commutable Certified Reference Material

Suppose a CRM is available that was validated to be *commutable* with patient samples for a given routine method with a specified value 10.0 mmol/L and a standard uncertainty of 0.2 mmol/L. Ten repeated measurements in independent runs give a mean value of 10.3 mmol/L with SD 0.5 mmol/L. The SE of the mean is then $[\sqrt{0.25}]$. The mean is not significantly different from the assigned value [$t = (10.3 - 10.0)/(0.2^2 + 0.16^2)^{0.5} = 1.17$]. The total standard uncertainty with regard to traceability is then $u_{Tracst} = (0.16^2 + 0.2^2)^{0.5} = 0.26$ mmol/L. If the bias had been significant, a correction to the method could have been carried out, and the standard uncertainty would then be the same at the given concentration. Thus measurements of the CRM provide an estimate of the uncertainty related to traceability, *given the assumption of commutability with patient samples*. The other components have to be estimated separately. Concerning method imprecision, long-term imprecision (e.g., observed from QC measurements) should be used rather than the short-term SD observed for CRM material. Here we suppose that the long-term SD_A is 0.8 mmol/L. Data on preanalytical variation can be obtained by sampling in duplicates from a series of patients or can be a matter of judgment (type B uncertainty) based on literature data or data on similar analytes. We here suppose that SD_{PA} equals half the analytical SD (i.e., 0.4 mmol/L). Finally, we lack data on a possible sample-related random bias component,

which we may choose to ignore in the present example. The standard uncertainty of the results then becomes

$$\begin{aligned} u_{\text{st}} &= [u_{\text{PAst}}^2 + u_{\text{ASt}}^2 + u_{\text{RBSt}}^2 + u_{\text{Tracst}}^2]^{0.5} \\ &= (0.4^2 + 0.8^2 + 0.26^2)^{0.5} \\ &= 0.93 \text{ (mmol/L)} \end{aligned}$$

In this case, the major uncertainty component is the long-term imprecision in the laboratory. To attain a reasonably precise uncertainty estimate, estimated SDs should be based on an appropriate number of repetitions. In the subsection on method precision, it can be seen that $N = 30$ repetitions provides SD estimates with 95% CIs extending from about 20% below to 35% above an estimated value (see Fig. 2.7), which may be regarded as reasonable.

Indirect Evaluation of Uncertainty by Quantification of Individual Error Source Components

On the basis of a detailed quantitative model of the analytical procedure, the standard approach is to assess the standard uncertainties associated with individual input parameters and combine them according to the law of propagation of uncertainties. The relationship between the combined standard uncertainty $u_c(y)$ of a value y and the uncertainty of the independent parameters $x_1, x_2, \dots, x_n$, on which it depends, is

$$u_c [y(x_1, x_2, \dots)] = [\sum c_i^2 u(x_i)^2]^{0.5}$$

where c_i is a sensitivity coefficient (the partial differential of y with respect to x_i). These sensitivity coefficients indicate how the value of y varies with changes in the input parameter x_i . If the variables are not independent, the relationship becomes

$$u_c [y(x_1, x_2, \dots)] = [\sum c_i^2 u(x_i)^2 + \sum c_i c_k u(x_i, x_k)^2]^{0.5}$$

where $u(x_i, x_k)$ is the covariance between x_i and x_k , and c_i and c_k are the sensitivity coefficients. The covariance is related to the correlation coefficient ρ_{ik} by

$$u(x_i, x_k) = u(x_i) u(x_k) \rho_{ik}$$

This is a complex relationship that usually will be difficult to evaluate in practice. In many situations, however, the contributing factors are independent, thus simplifying the picture. Below, some simple examples of combined expressions are shown. The rules are presented in the form of combining SDs or CVs given independent input components.

$$q = x + y \quad \text{SD}(q) = [\text{SD}(x)^2 + \text{SD}(y)^2]^{0.5}$$

$$q = x - y \quad \text{SD}(q) = [\text{SD}(x)^2 + \text{SD}(y)^2]^{0.5}$$

$$q = ax \quad \text{SD}(q) = a \text{SD}(x) \quad \text{and} \quad \text{CV}(q) = \text{CV}(x)$$

$$q = x^p \quad \text{CV}(q) = p \text{CV}(x)$$

$$q = xy \quad \text{CV}(q) = [\text{CV}(x)^2 + \text{CV}(y)^2]^{0.5}$$

$$q = x/y \quad \text{CV}(q) = [\text{CV}(x)^2 + \text{CV}(y)^2]^{0.5}$$

The formulas shown may be used, for example, to calculate the combined uncertainty of a calibrator solution from the uncertainties of the reference compound, the weighting, and dilution steps. In some situations, a Monte Carlo simulation model of a complex analytical method may be established to estimate the combined uncertainty of the method on the basis of input uncertainties.

POINTS TO REMEMBER

- For well-established analytes, a hierarchy of methods exists with a *reference measurement procedure* at the top, *selected measurement procedures* at an intermediate level, and finally *routine measurement procedures* at the bottom.
- The uncertainty is given as an interval around a reported laboratory result that specifies the location of the true value with a given probability (e.g., 95%).
- The uncertainty of a result, which is traceable to a particular reference, is the uncertainty of that reference together with the overall uncertainty of the traceability chain.
- The uncertainty can be judged *directly* from measurement comparisons ("top down") or *indirectly* from an analysis of individual error sources according to the law of error propagation ("error budget," "bottom up").

DIAGNOSTIC ACCURACY OF LABORATORY TESTS

We here consider the basic steps for evaluation of the clinical accuracy of laboratory tests. In diagnostic accuracy studies, the measurements or results of one (or more) laboratory test under evaluation (i.e., the so-called index test) are compared with the results of a reference standard or method. This reference is the best prevailing test or strategy that is used to establish the presence or absence of the disease of interest (i.e., the so-called target disease that is to be detected or excluded by the index tests). This reference standard is conducted and its results interpreted as blindly for and independently from the index test(s) results as possible. Test accuracy studies show the concordance in results of the index test(s) with the presence or absence of disease as defined by the reference standard results. These studies provide information regarding the frequency of types of errors (i.e., false positive and negative test results) by the index test in relation to the reference standard.

Diagnostic Accuracy, Sensitivity, and Specificity of a Test in Isolation

In a diagnostic accuracy study the results of the index test are compared with those of a reference test in the same

Test result	Disease status	
	Diseased	Nondiseased
Positive	TP	FP
Negative	FN	TN

Fig. 2.24 The basic 2-by-2 table for estimating the diagnostic accuracy of a dichotomized quantitative test result. Positive test results are divided into true positives (TPs) and false positives (FPs) and negative results into true negatives (TNs) and false negatives (FNs). (From Linnet, K., Bossuyt, P. M., Moons, K. G., & Reitsma, J. B. [2012]. Quantifying the accuracy of a diagnostic test or marker. *Clinical Chemistry*, 58, 1292–1301.)

individuals, all of whom are suspected to have the target disease (the suspected disease cohort design). The simplest situation is a comparison of a single index test, with only two result categories (i.e., a dichotomous or binary index test) to a reference standard (i.e., a single-test accuracy study). The ideal dichotomous index test correctly identifies all individuals as diseased or nondiseased with an error rate of zero. A zero error rate is only possible when there is no overlap between index test results in the diseased and nondiseased individuals. However, when there is overlap in index test results, some individuals are classified wrongly as shown below in an example concerning the diagnosis of deep venous thrombosis (DVT) using a D-dimer index test. When using a quantitative (continuous) index test to classify individuals as diseased or nondiseased, a cutoff value needs to be chosen to estimate these error rates. This results in a so-called dichotomized index test.

Values of the dichotomous or dichotomized index test that exceed the cutoff in individuals having the target disease are classified as true positives (TP) (Fig. 2.24). Similarly, index test results lower than the cutoff in nondiseased individuals are true negatives (TN). Accordingly, index test results below the cutoff in truly diseased subjects are false negative (FN), and index test results exceeding the cutoff in truly nondiseased subjects are false positive (FP). Based on the frequencies of FN and FP results, an overall error rate or non-error rate can be derived. The overall diagnostic accuracy of an index test is then defined as the fraction of true classifications out of all classifications:

$$\text{Diagnostic accuracy} = (TN + TP) / (TN + TP + FP + FN)$$

This is an overall non-error rate that can be subdivided into the non-error rate of the nondiseased individuals, which is the specificity of the test and the non-error rate of diseased individuals which is the sensitivity of the test

$$\text{Specificity} = TN / (TN + FP)$$

$$\text{Sensitivity} = TP / (TP + FN)$$

Whereas a very specific test provides negative results for all or almost all subjects who are free of the target disease, a very sensitive test detects all or almost all diseased subjects. To assess the (im)precision of these estimates, CIs should be specified as described under *Categorical Variables*. Table 2.3 displays the widths of the 95% CIs at various sample sizes of

TABLE 2.3 Relationship Between Sample Size and 95% Confidence Intervals of a Proportion (e.g., a Sensitivity or Specificity): Selected Examples of Proportions of 0.05 and 0.80

Sample Size	95% CI of a Proportion of 0.05	95% CI of a Proportion of 0.80
20	0.00–0.25	0.56–0.94
60	0.01–0.14	0.68–0.90
100	0.02–0.11	0.71–0.87
500	0.03–0.07	0.76–0.83
1000	0.04–0.07	0.77–0.82

CI, Confidence interval.

Relative frequency of study patients

Fig. 2.25 Distribution of the quantitative D-dimer values for deep venous thrombosis (DVT) and non-DVT subjects in the example study. Light blue line, non-DVT; blue line, DVT. The dashed line indicates the commonly used cutoff value of 500 µg/L. (From Linnet, K., Bossuyt, P. M., Moons, K. G., & Reitsma, J. B. [2012]. Quantifying the accuracy of a diagnostic test or marker. *Clinical Chemistry*, 58, 1292–1301.)

20 to 1000 for two selected proportions. The specificity and sensitivity of two tests applied in the same study subjects can be statistically compared using the McNemar's test.

Clinical Example: Accuracy of D-Dimer Test in Diagnosis of Deep Venous Thrombosis

We illustrate the concepts using some of the empirical data of a previously published study in primary care patients suspected of having DVT, the target disease (Fig. 2.25).

The study consisted of 2086 patients suspected of DVT, where DVT was defined as present in patients manifesting at least one of the following symptoms or signs: presence of swelling, redness, or pain in the leg. All patients were given a standardized diagnostic workup, including medical history; clinical examination; and testing for D-dimer, the (quantitative) index test. The reference procedure consisted of repeated compression ultrasonography tests and was performed in all patients, blinded to and independent of the index test results. A total of 416 (20%) of the 2086 included patients had DVT.

Fig. 2.26 Receiver operating characteristic curve of the D-dimer assay result for diagnosis of deep venous thrombosis in our example study. The blue markers correspond to various cutoff choices (from left to right, 5435 µg/L, 2133 µg/L, and 500 µg/L). (From Linnet, K., Bossuyt, P. M., Moons, K. G., & Reitsma, J. B. [2012]. Quantifying the accuracy of a diagnostic test or marker. *Clinical Chemistry*, 58, 1292–1301.)

Applying a commonly used cutoff of 500 µg/L or greater for the (originally) quantitative D-dimer assay (dashed line in Fig. 2.25), the sensitivity was 0.97 (i.e., 3% of the subjects with DVT had a value <500 µg/L). The specificity was only 0.37. The resulting overall diagnostic accuracy was 0.50. Whereas the test displayed good sensitivity at this threshold, detecting all but 3% of those having DVT, its specificity at this test threshold was relatively low, resulting in many FP results. The SEs were 0.012 for the specificity and 0.008 for the sensitivity, resulting in CIs of 0.356 to 0.402 and 0.955 to 0.987, respectively.

Receiver Operating Characteristic Curves

For a quantitative index test, the specificity and sensitivity depend on the selected cutoff point. A plot of the sensitivity and specificity pairs for all possible cutoff values over the measurement range provides the so-called **receiver operating characteristic (ROC) curve** (Fig. 2.26). Usually, sensitivity (y) is plotted against $(1 - \text{specificity})$ (x) at each possible cutoff value. The better the performance of the test, the higher the ROC curve is located in the left, upper region of the plot. With use of the ROC curve, an appropriate combination of specificity and sensitivity may be chosen, and the corresponding cutoff then selected.

An area under the ROC curve (i.e., the ROC area or so-called concordance or c -index) can be assessed by either parametric or nonparametric statistics. Given an SE of the ROC area or c -index, it is possible to test whether the area significantly exceeds 0.5, which would demonstrate that the index test performs better than chance. A worthless test has an area of 0.5. Furthermore, using the SE, also a 95% CI can be derived for the ROC area or c -index. For the D-dimer test example, the area under the ROC curve was 0.86 (SE, 0.011), with a 95% CI of 0.84 to 0.88.

Fig. 2.27 Alternative cutoffs to 500 µg/L in the D-dimer example. (A) Cutoff (2133 µg/L) giving maximum value of the sum of the specificity and sensitivity. (B) Cutoff (5435 µg/L) providing a high specificity (0.975). Light blue line, non-deep venous thrombosis (DVT); blue line, DVT. The dashed line indicates the cutoff value. (From Linnet, K., Bossuyt, P. M., Moons, K. G., & Reitsma, J. B. [2012]. Quantifying the accuracy of a diagnostic test or marker. *Clinical Chemistry*, 58, 1292–1301.)

Selection of Cutoff Value in Case of Quantitative Index Tests

The specificity and sensitivity determined for an index test almost always vary inversely over the range of possible cutoffs. The cutoff point that provides the maximum of the sum of the specificity and sensitivity *could* be selected. In the D-dimer example, this cutoff would be close to 2000 µg/L, yielding a specificity of 0.76 and a sensitivity of 0.80 (Fig. 2.27A). However, this method of cutoff selection is commonly not recommended. The selection should rather be based on the intended purpose of the index test. If an index test is applied primarily to rule out the presence of disease (e.g., in the case of the D-dimer assay for exclusion of DVT), the cutoff point

should be at the lower end of the distribution of values of diseased individuals (see Fig. 2.25) (e.g., a cutoff of 500 $\mu\text{g/L}$). At this cutoff, the sensitivity approaches 1.0. But attaining such a high sensitivity is at the cost of a loss of specificity because of overlap of test values in the diseased and nondiseased individuals. Conversely, when FP results are judged unacceptable, the cutoff should be toward the upper limit of the distribution of values for the nondiseased group. For the D-dimer test example, a cutoff value corresponding to the 97.5 percentile of the distribution of values for those not having DVT (5435 $\mu\text{g/L}$) resulted in a specificity of 0.975, but now the sensitivity was only 0.36 (i.e., nearly the opposite of the situation with a cutoff of 500 $\mu\text{g/L}$) (see Fig. 2.27B).

Posterior Probabilities (Predictive Values)

Unlike sensitivity and specificity, the **positive predictive value** assesses the probability of having the disease given a positive test result, $P(D|T_{\text{pos}})$, whereas the **negative predictive value** assesses the probability of not having the disease given a negative test result $P(\text{Non} - D|T_{\text{neg}})$. The probability of presence of target disease given the index test result is an example of a so-called posterior disease probability, where the prior probability corresponds to the prevalence of the disease in the given situation. The **prevalence** of disease ($P(D)$) in the study sample is the a priori (pretest) probability of disease.

Given a positive test result (T_{pos}), the posterior disease probability is estimated as the fraction of TP out of all test result positives:

$$P(D|T_{\text{pos}}) = TP / (TP + FP)$$

Analogously for a negative result (T_{neg}), the probability that the given disease is absent is

$$P(\text{Non} - D|T_{\text{neg}}) = TN / (TN + FN)$$

Just as with sensitivity and specificity values, these posterior disease probabilities depend on the selected cutoff point for a quantitative test. In case of a dichotomous or dichotomized index test, these posterior probabilities are also called predictive values. They are highly dependent on the disease prevalence.

From the Bayes rule, the following relations exist:

$$P(D|T_{\text{pos}}) = [\text{Sensitivity} \times P(D)] / [\text{Sensitivity} \times P(D) + (1 - \text{Specificity}) (1 - P(D))]$$

$$P(\text{Non} - D|T_{\text{neg}}) = [\text{Sensitivity} \times (1 - P(D))] / [\text{Specificity} \times (1 - P(D)) + P(D) \times (1 - \text{Specificity})]$$

Likelihood Ratios and Odds Ratios

From relative frequency distributions for results of the index test in the nondiseased and diseased groups, the so-called diagnostic **likelihood ratio** (LR) of an index test result (X) can be calculated as the ratio between the heights of the relative frequency (f) distributions at that specific test value. We get:

$$LR(X) = f_D(X) / f_{\text{Non} - D}(X)$$

In case the relative frequency of the distribution of diseased individuals is higher than that of the nondiseased individuals, the ratio exceeds 1. This indicates that disease is more likely than nondisease given this particular index test result. More formally, the ratio can be used to calculate posterior disease probabilities given specific values of the index test (X) and the disease prevalence (D):

$$P(D|X) = P(D) \times LR(X) / [P(D) \times LR(X) + (1 - P(D))]$$

or a more simple calculation can be carried out using odds instead of probabilities:

$$\text{Odds}(D|X) = \text{Odds}(D) \times LR(X)$$

based on the relation:

$$\text{Odds} = P / (1 - P)$$

Odds is an alternative way of expressing probabilities commonly used in betting games in Anglo-Saxon countries. For example, a probability of 0.80, or 80%, corresponds to an odds value of 4 according to the formula above. The higher the odds, the closer a probability is to one. From the equation, the posterior odds are equal to the prior odds multiplied by the diagnostic LR for the result X .

For a dichotomous or dichotomized index test, the following relationships apply:

$$LR(\text{pos}) = \text{Sensitivity} / (1 - \text{Specificity})$$

$$LR(\text{neg}) = (1 - \text{Sensitivity}) / \text{Specificity}$$

A simple way of achieving the posttest probability of disease from the prevalence (pretest probability of disease) and the diagnostic LR is to use the Fagan nomogram. A recent example is the estimation of the probability of DVT from testing for D-dimer.

Comparison of Diagnostic Accuracy of Two Tests in Isolation

The diagnostic accuracy—that is, the ability to detect or exclude the target disease as determined by the reference method—of a new diagnostic index test is usually compared with another, established, index test. We here focus on the pure performances of the tests without consideration of other tests (i.e., we consider each test in isolation). When comparing the accuracy of two or more diagnostic index tests, a paired design is generally preferable for reasons of both validity and efficiency. In the target disease-suspected patients, the two index tests under comparison and the reference standard are performed on all subjects, again independently and blinded with regard to each other's test results. An example of a paired comparison is displayed in Fig. 2.28. Overall, the index test having the largest area under the ROC curve represents the best test. Preferably, CIs of areas and differences of areas should be provided.

Fig. 2.28 Comparison of the receiver operating characteristic curves of two hypothetical index tests for the same target disease undertaken in the same individuals. The *dotted blue curve* represents a superior diagnostic test, both with regard to sensitivity and specificity over all possible cutoff points. The *dashed diagonal* represents a worthless test, with equal probability of a false-positive ($1 - \text{Specificity}$) and false-negative ($1 - \text{Sensitivity}$) result across all cutoff values (i.e., flipping a coin test). (From Linnet, K., Bossuyt, P. M., Moons, K. G., & Reitsma, J. B. [2012]. Quantifying the accuracy of a diagnostic test or marker. *Clinical Chemistry*, 58, 1292–1301.)

The STARD (Standards for Reporting of Diagnostic Accuracy Studies) initiative (Box 2.2) and the so-called QUADAS-2 (Quality Assessment Tool for Diagnostic Accuracy Studies) aim at improving diagnostic accuracy studies (<http://www.quadas.org>).

Diagnostic Accuracy of a Test in the Clinical Context

The diagnostic process commonly consists of a series of sequential steps in which much diagnostic information (i.e., diagnostic test results) is acquired. After each step, the physician intuitively judges the probability of the target disease being present. The initial step always consists of patient history and physical signs. If uncertainty about the presence and type of disease remains, subsequent tests are performed, often in another stepwise fashion. These supplementary tests may consist of simple blood or urine tests or be imaging, electrophysiology, or genetic tests or even later in the process more invasive testing such as biopsy, angiography, or arthroscopy. The supplementary information of each subsequent test is implicitly added to the already collected diagnostic information, and the target disease probability is constantly updated. This process continues until the target disease can be included or excluded with sufficient certainty.

Diagnostic test studies should reflect the steps in the diagnostic process so that the added value of such tests in excess

of the information that is already present can be assessed. Depending on the situation, studies may reveal that the diagnostic information of any subsequent test is already supplied by the simpler previous test results. When regarded in isolation, such subsequent test or marker may indeed show diagnostic accuracy or value, but when assessed in the overall diagnostic workup, it does not. Such a case can arise because different tests may gauge the same underlying pathologic processes to varying degrees and thus provide related diagnostic information.

Clinical Example: Added Value of D-Dimer Testing in the Diagnosis of Suspected Deep Venous Thrombosis

The same DVT case study described earlier is considered. A total of 2086 patients were suspected of DVT, having at least one of the following symptoms: swelling, redness, or pain in the leg. All patients had a standardized diagnostic workup consisting of index tests from medical history taking, physical examination, and quantitative D-dimer testing. The reference standard was repeated compression ultrasonography, according to current clinical practice, carried out in all patients independent of the results of the index tests and blinded with regard to all preceding collected index test results. In total, 416 of the 2068 included patients (20%) had DVT confirmed by ultrasonography. We focus on estimating the added value of D-dimer testing to the information provided by history taking and physical examination.

A multivariable statistical approach is needed to assess the diagnostic accuracy of combined index test results. Logistic regression models express the probability of DVT (on the logit scale) as a linear function of the included index test results. Note that index test results may be included as binary, categorical, or even continuous results. Table 2.4 (model 1) shows the results from history and physical examination test results that were significantly related to DVT in the multivariable analysis, here defined as a multivariable **odds ratio** significantly ($P < .05$) different from 1 (no association).

To quantify whether the quantitative D-dimer assay result has added diagnostic value beyond the history and physical examination results combined, the basic model 1 was simply extended by including the index test D-dimer value, resulting in model 2 (see Table 2.4). After the inclusion of the D-dimer assay result, the regression coefficients of most history and physical tests in model 2 are found to be different from those in model 1: They now express the contribution of the corresponding test results, given a specific D-dimer result. This change reveals that the history and physical and the D-dimer results are indeed correlated and partly provide the same diagnostic information regarding whether DVT is present or not. The trend of lower regression coefficients of most findings can be interpreted as follows: A portion of the information supplied by the history and physical items is now replaced by the D-dimer assay result.

BOX 2.2 STARD 2015: An Updated List of Essential Items for Reporting Diagnostic Accuracy Studies

Title or Abstract

1. Identification as a study of diagnostic accuracy using at least one measure of accuracy (e.g., sensitivity, specificity, predictive values, AUC)

Abstract

2. Structured summary of study design, methods, results, and conclusions (for specific guidance, see STARD for Abstracts)

Introduction

3. Scientific and clinical background, including the intended use and clinical role of the index test
4. Study objectives and hypotheses

Methods

Study Design

5. Whether data collection was planned before the index test and reference standard were performed (prospective study) or after (retrospective study)

Participants

6. Eligibility criteria
7. On what basis potentially eligible participants were identified (e.g., symptoms, results from previous tests, inclusion in registry)
8. Where and when potentially eligible participants were identified (setting, location, and dates)
9. Whether participants formed a consecutive, random, or convenience series

Test Methods

- 10a. Index test, in sufficient detail to allow replication
- 10b. Reference standard, in sufficient detail to allow replication
 11. Rationale for choosing the reference standard (if alternatives exist)
- 12a. Definition of and rationale for test positivity cutoffs or result categories of the index test, distinguishing prespecified from exploratory
- 12b. Definition of and rationale for test positivity cutoffs or result categories of the reference standard, distinguishing prespecified from exploratory
- 13a. Whether clinical information and reference standard results were available to the performers or readers of the index test

- 13b. Whether clinical information and index test results were available to the assessors of the reference standard

Analysis

14. Methods for estimating or comparing measures of diagnostic accuracy
15. How indeterminate index test or reference standard results were handled
16. How missing data on the index test and reference standard were handled
17. Any analyses of variability in diagnostic accuracy, distinguishing prespecified from exploratory
18. Intended sample size and how it was determined

Results

Participants

19. Flow of participants, using a diagram
20. Baseline demographic and clinical characteristics of participants
- 21a. Distribution of severity of disease in those with the target condition
- 21b. Distribution of alternative diagnoses in those without the target condition
22. Time interval and any clinical interventions between index test and reference standard

Test Results

23. Cross-tabulation of the index test results (or their distribution) by the results of the reference standard
24. Estimates of diagnostic accuracy and their precision (e.g., 95% CIs)
25. Any adverse events from performing the index test or the reference standard

Discussion

26. Study limitations, including sources of potential bias, statistical uncertainty, and generalizability
27. Implications for practice, including the intended use and clinical role of the index test

Other Information

28. Registration number and name of registry
29. Where the full study protocol can be accessed
30. Sources of funding and other support; role of funders

AUC, Area under the curve; CI, confidence interval; STARD, Standards for Reporting of Diagnostic Accuracy Studies.

From Bossuyt, P. M., Reitsma, J. B., Bruns, D. E., Gatsonis, C. A., Glasziou, P. P., Irwig, L., et al. (2015). STARD 2015: an updated list of essential items for reporting diagnostic accuracy studies. *Clinical Chemistry*, 61(12), 1446–1452.

Diagnostic Accuracy of Combinations of Diagnostic Tests: Receiver Operating Characteristic Area

The multivariable diagnostic model, which is based on a combination of diagnostic index tests, as exemplified in models 1 and 2 in Table 2.4, can be considered as a single (overall or combined) quantitative index test, consisting of a composite of individual index tests. The test result of this “combined index test model” for each study patient is simply the

calculated posterior probability of DVT presence given the observed pattern of the individual index test results in that patient. (See the footnote to Table 2.4 on how to calculate this probability of disease presence.)

As for single continuous index tests described earlier, also for “test combinations” combined into a single multivariable model, the ROC area (*c*-statistic) can be calculated to indicate the ability of this “test combination” to discriminate between

TABLE 2.4 Basic and Extended Multivariable Diagnostic Model to Discriminate Between Deep Venous Thrombosis Presence Versus Absence^a

	MODEL 1 (BASIC MODEL)			MODEL 2 (BASIC MODEL + D-DIMER)		
	Regression Coefficient (SE)	OR (95% CI)	P value	Regression Coefficient (SE)	OR (95% CI)	P value
(Intercept)	−3.70 (0.26)	—	<.01	−4.94 (0.32)	—	<.01
Presence of malignancy	0.62 (0.22)	1.9 (1.2–2.9)	<.01	0.22 (0.26)	1.2 (0.7–2.1)	0.41
Recent surgery	0.44 (0.16)	1.6 (1.1–2.1)	<.01	0.003 (0.19)	1.0 (0.7–1.5)	0.99
Absence of leg trauma	0.75 (0.18)	2.1 (1.5–3.0)	<.01	0.67 (0.20)	2.0 (1.3–2.9)	<.01
Vein distension	0.48 (0.13)	1.6 (1.1–2.1)	<.01	0.25 (0.16)	1.3 (0.9–1.8)	0.12
Pain on walking	0.41 (0.15)	1.5 (1.1–2.0)	<.01	0.46 (0.18)	1.6 (1.1–2.3)	0.01
Swelling whole leg	0.36 (0.12)	1.4 (1.1–1.8)	<.01	0.47 (0.14)	1.6 (1.2–2.1)	<.01
Difference in calf circumference (per cm)	0.36 (0.04)	1.4 (1.3–1.5)	<.01	0.29 (0.04)	1.3 (1.2–1.4)	<.01
D-Dimer (per 500 ng/mL)	NA	NA	NA	0.29 (0.02)	1.3 (1.3–1.4)	<.01

^aExp (regression coefficient) is the odds ratio (OR) of a diagnostic test result. For example, an odds ratio of 2 for absence of leg trauma (model 2) means that a suspected patient without a recent leg trauma has a two times higher chance of having deep venous thrombosis (DVT) than a patient with a recent leg trauma (because in the latter the leg trauma would more likely be the cause of the presenting symptoms and signs). Similarly, an odds ratio of 1.3 for calf difference in cm (model 2) means that for every centimeter increase in calf circumference difference, a patient has a 1.3 times (or 30%) higher chance of having DVT.

A diagnostic model can be considered as a single overall or combined test consisting of different test results, with the probability of DVT presence as its test result. For example, for a male subject without malignancy, recent surgery, or leg trauma but with vein distension and a painful not swollen leg when walking with a calf difference of 6 cm the formula is (model 1):

$$Z = -3.70 + 0.62*0 + 0.44*0 + 0.75*0 + 0.48*1 + 0.41*1 + 0.36*0 + 0.36*6 = -0.65$$

The probability for this patient of the presence of DVT based on the basic model then is $\exp(-0.65)/(1 + \exp(-0.65)) = 34\%$.

CI, Confidence interval; NA, not applicable; SE, standard error.

Fig. 2.29 Receiver operating characteristic (ROC) curves for the combination of history and physical examination tests before and after addition of the D-dimer assay result. (From Moons, K. G., de Groot, J. A., Linnet, K., Reitsma, J. B., & Bossuyt, P. M. [2012]. Quantifying the added value of a diagnostic test or marker. *Clinical Chemistry*, 58, 1408–1417.)

the presence versus absence of the target disease (here DVT). Fig. 2.29 shows the ROC curves and areas for models 1 and 2. Adding the quantitative D-dimer assay to model 1 mediated an increase in the ROC area from 0.72 to 0.87, a considerable and statistically significant gain ($P < .01$).

Impact of Diagnostic Tests

When thinking about approaches to evaluate the impact of diagnostic tests on medical decision making, patient outcomes, and healthcare at large, it is useful to describe the pathways through which benefits (and risks) of using the test are likely to occur. This so-called *working pathway* provides a framework (Fig. 2.30) to explain how a given test leads to benefits or risks for patients' health or healthcare. Such working pathways include:

1. The anticipated technical or analytical capabilities of the test
2. The unintended and intended results and effects of the test (e.g., benefits of diagnosis and treatment) when applied in the targeted context
3. Those individuals in whom these effects are likely to occur (e.g., in the targeted patients or in the care providers)
4. The anticipated mechanisms through which these potential effects will occur
5. Existing care in the targeted context and individuals
6. The expected time frame in which potential risks and benefits might occur

A clear description of the working pathway of a new test can determine the current benefits (and risks) of prevailing care in the intended medical context. It also helps determine what added value or benefits the new test must provide to improve existing care and what evidence is necessary to quantify whether these (added) benefits are indeed achieved at what risks or costs.

Fig. 2.30 Relationship between the pathway through which devices may lead to benefits or added benefits for health or health care and the three dimensions of quality for evidence (indirectness of evidence, risk of bias, precision of estimates). (From KNAW. [2014]. *Evaluation of new technology in health care. In need of guidance for relevant evidence*. Amsterdam: KNAW.)

POINTS TO REMEMBER

- The diagnostic accuracy of a test indicates the frequency and type of errors that a test will produce when differentiating between patients with and without the target disease.
- The cohort design based on patients suspected of the diseases targeted by the index test is generally preferable for evaluating diagnostic accuracy.
- It is not meaningful to regard estimates of diagnostic performance as properties of the test itself but rather to interpret

them as depending on the setting in which the index test was applied and dependent on other tests that are commonly used in that setting.

- Focus has been on approaches and measures for quantification of the diagnostic accuracy of combinations of index tests and of the added value of a new diagnostic test beyond existing diagnostic tests.

REVIEW QUESTIONS

- Which statement applies to a sample of values drawn from a Gaussian distribution?
 - The central location is best described by the median.
 - The dispersion is best described by the interquartile range.
 - The distribution of the values is likely to be asymmetric.
 - The t distribution is useful for estimation of the 95% CI for the mean value.
- The analytical specificity of an assay is:
 - the ability of an assay procedure to determine the concentration of a target analyte in the presence of interfering substances in the sample matrix.
 - the detection limit of a method.
 - the ability of an analytical method to assess small variations in the concentration of analyte.
 - the analyte concentration range over which measurements are within the declared tolerances for imprecision and bias of the method.
- Two analytical methods are to be compared by analysis in parallel of a suitable number of patient samples. Which of the following is correct?
 - Ordinary least-squares regression analysis is the most appropriate data analysis approach.
 - It is generally recommended that the manufacturer use 40 samples for comparison and the user laboratory 100 samples.
 - A calibration difference is most typically disclosed by an intercept estimate significantly different from zero obtained by regression analysis.
 - In case of constant CV%, the Bland-Altman difference plot shows an increasing scatter of the measured differences at increasing measurement values.

4. In a regression analysis comparing results of two methods, the y -intercept is calculated to be 2.0 and the slope is 3. This indicates a(n):
 - a. calibration error.
 - b. uncertainty.
 - c. systematic difference.
 - d. interference in one method.
5. Which one of the following, when stated as an interval around a reported laboratory result, will specify the location of the true value with a given probability?
 - a. Traceability
 - b. Coefficient of variation
 - c. Trueness
 - d. Uncertainty
6. The traceability chain extends downwards from the reference measurement procedure to the routine analytical method. Which of the following is correct?
 - a. A reference measurement procedure is sensitive to matrix effects.
 - b. The standard uncertainty indicates a 95% uncertainty interval.
 - c. Harmonization of laboratory measurements do not presuppose traceability to a reference measurement procedure.
 - d. The reference measurement procedure is always more precise than the routine analytical method.
7. The diagnostic accuracy of a test is assessed on a number of subjects suspected of having a given target disease. Which of the following is correct?
 - a. The diagnostic accuracy is characteristic for the test and is not influenced by the actual setting in which it is evaluated.
 - b. The ROC area provides a measure of the diagnostic accuracy, which is not dependent on a selected cut-off value.
 - c. When the cut-off value of a quantitative test is increased, the specificity declines and the sensitivity increases.
 - d. In order to rule out the presence of disease, it is important that the specificity is high.
8. The probability of the presence of a specific disease divided by the probability of its absence is the:
 - a. likelihood ratio.
 - b. odds ratio.
 - c. prevalence.
 - d. predictive value.
9. When a receiver operating characteristic curve is plotted, the x -axis represents the:
 - a. false-positive rate.
 - b. true-positive rate.
 - c. false-negative rate.
 - d. true-negative rate.
10. A new test is added to an existing set of diagnostic procedures. Which of the following is correct?
 - a. The diagnostic accuracy of the new test is the most important point to consider.
 - b. A multivariate data treatment based on logistic regression analysis presupposes quantitative test results.
 - c. It is unlikely that results from several tests are correlated.
 - d. The difference between the ROC curve area after addition of the new test and the area of the ROC curve of the original diagnostic procedure expresses the added value of the new test.

Preanalytical Variation

Ana-Maria Simundic

OBJECTIVES

1. List major sources of variability in preanalytical phase.
2. Define the following terms:
 - Modifiable and unmodifiable influencing factors
 - Endogenous and exogenous interference factors
 - In vivo and in vitro hemolysis
 - Lipemia
 - Icterus
 - First morning urine
 - Timed urine specimen
 - First void urine
 - Midstream urine
 - Suprapubic urine aspiration
 - Unstimulated whole saliva
 - Stimulated saliva
3. State how to deal with modifiable and nonmodifiable influencing factors.
4. Summarize the requirements for a proper definition of the fasting state.
5. Describe mechanisms through which hemolysis, icterus, and lipemia affect various assays and parameters.
6. Describe ways of removal of lipids from the sample.
7. Identify major preanalytical issues related to some specific laboratory tests or sample types.
8. Define optimal sample type for blood gas analysis.
9. Describe proper procedure for saliva collection.
10. Explain the difference between stimulated and unstimulated saliva collection.
11. List advantages and challenges of using saliva as a diagnostic specimen.
12. Describe how cold agglutinins, cryoglobulins, and ethylenediaminetetraacetic acid “(EDTA)-dependent antibodies” interfere with hematologic analytes:

KEY WORDS AND DEFINITIONS

Cold agglutinins Antibodies specific for erythrocyte surface carbohydrate antigens, which bind to the erythrocyte surface at 0°C to 4°C.

Cryoglobulins Immunoglobulins with temperature-dependent solubility that precipitate at temperatures below 37°C.

Endogenous interferences Interferences that originate from the substances present in the patient sample.

Exogenous interferences The effect of various substances added to the patient sample (anticoagulants, gel particles, infusions, etc.).

First morning urine A urine specimen that is collected immediately after arising from bed after an overnight sleep (also called *overnight* or *early morning* urine).

First void urine The first portion of the urine (usually first 15 to 50 mL) passed at any time of the day.

Hemolysis A process of membrane disruption of erythrocytes and other blood cells, accompanied by the subsequent release of cell components into the plasma and red coloration of the serum or plasma after centrifugation.

Icterus A clinical condition that is associated with a change of the color of the serum due to the increase of bilirubin concentration above 5.9 mg/dL or 100 μmol/L.

In vitro hemolysis Hemolysis that occurs outside of the patient at various steps of the preanalytical phase (during blood sampling, sample handling, delivery to the laboratory, and sample storage).

In vivo hemolysis Hemolysis that occurs within the body, before the blood has been drawn and is a result of a pathologic condition.

Influencing factors In vivo and in vitro effects on laboratory results of biological origin that modify the concentration of the affected analyte in a method independent way.

Interference factors Compounds and mechanisms in a biological specimen that alter the result of an analyte thus leading to falsely increased or decreased laboratory test results for that analyte.

Laboratory error Any error that occurs throughout the total testing process (i.e., preanalytical phase, analytical phase, and postanalytical phase).

Lipemia Turbidity of the sample visible to the naked eye, which is caused by light scattering due to the presence of large lipoprotein particles.

Midstream urine A urine specimen collected during the middle of a urine flow after the urinary opening has been carefully cleaned (also called *clean catch urine specimen*).

Modifiable influencing factors Influencing factors that can be controlled by patient action.

Preanalytical phase Part of the total testing process that encompasses test requesting, patient preparation, sampling, sample transport, and delivery to the laboratory, and sample handling before analysis.

Stimulated saliva A saliva sample obtained by the stimulation of salivation with citric acid or by oral movements (yawning, chewing paraffin or gum) and collected through adsorbing saliva by cotton rolls, cotton swabs, or filter paper.

Suprapubic aspiration A specific way of urine collection performed by aspirating urine from the distended bladder through the abdominal wall.

Timed urine specimen A urine specimen that is collected at a specified time or in relation to some activity (e.g., before a meal, after a meal, before therapy, exercise, etc.) during a 24-hour period.

Unmodifiable influencing factors Factors that lead to unavoidable changes in analyte concentration and cannot be controlled by patient action.

Unstimulated whole saliva A saliva sample collected either passively or by spitting into a collector vial.

PREANALYTICAL PHASE

The annual incidence of premature patient deaths associated with some form of preventable medical error in the United States has been estimated to be 98,000 per year. More recent data indicate that the actual mortality caused by preventable medical errors might even be fourfold higher. **Laboratory errors** significantly contribute to the overall error frequency in healthcare. They can lead to diagnostic errors (i.e., missed diagnosis, misdiagnosis, and delayed diagnosis) and consequent patient harm, and increased healthcare expenditure. The **preanalytical phase** is recognized as the most vulnerable part of the total testing process and it accounts for two-thirds of all laboratory errors and may be attributed to various causes. Many preanalytical steps are performed outside the laboratory and are not under the direct supervision of laboratory staff. Furthermore, many individuals are involved in various preanalytical steps and those individuals have different levels of education and professional background. Finally, safe practice standards for many activities and procedures are: (1) either not available, or (2) are available but are not evidence based, or (3) there is low level of compliance with those standards.

The ISO 15189 accreditation standard clearly defines that medical laboratories are responsible for the management and quality of the preexamination phase. It is the role of the laboratorian to ensure that the right sample is taken from the right patient, at the right time, and that correct test results are provided to the requesting physician in a timely manner. If the quality of the specimen is compromised to a degree where the expected effect is larger than the allowable error, causing clinically significant bias, the sample should be rejected for analysis. The guiding principle should be: "No result is always better than a bad result."

Influencing and Interference Factors

Influencing Factors

Influencing factors are effects on laboratory results of biological origin which can occur in vivo (most common) and in vitro (during sample transport and storage). Biological factors modify the concentration of the analyte in a method independent way.

These factors are either present in the healthy individual, like circadian rhythms, or appear as an effect of a disease and its treatment. Examples of **modifiable influencing factors** are diet, time of the day, or time of the year (season), whereas **unmodifiable influencing factors** are gender, ethnicity, genetic background, etc.

Modifiable Influencing Factors

Changes occurring due to the time of sampling may affect the concentrations of various analytes. These changes can be linear (in a chronological order) and cyclic (of a repetitive nature, such as seasonal changes, or changes due to the menstrual cycle).

Several analytes tend to fluctuate in terms of their plasma concentration over the course of a day (i.e., circadian rhythm). For example, the concentration of cortisol is highest in the morning and lowest at night. To avoid the potential effect of analyte changes during the day, reference intervals are defined for blood sampling between 7 and 9 a.m.

Besides the circadian rhythm, some analytes can exhibit significant changes due to the biological changes that occur in hormone patterns during menstruation. For example, aldosterone concentration in plasma is twice as high before ovulation as in the follicular phase.

Diet also may substantially affect the composition of plasma. Differences in serum composition may occur respective to the source of nutrients, the number of meals, and the proportion of nutrients in a diet. Effects from diet can be either long term or acute. Long-term effects of diet may occur over a couple of days, or longer. For example, a diet rich in fat leads to increased serum triglyceride concentration, whereas diet rich in carbohydrates decreases serum protein and lipid concentrations. Vegetarians tend to have lower concentrations of plasma cholesterol, triglycerides, and creatinine with reduced urinary excretion of creatinine, and a higher urinary pH, as a result of reduced intake of precursors of acid metabolites. Most of the changes described are corrected following the restoration of good nutrition.

Acute effects of diet and other influencing factors occur immediately or shortly after ingestion of food or fluid intake. For example, the decrease of plasma glucose and increase of lactate are the acute effects of ethanol consumption, which

occur as early as 2 to 4 hours after the ingestion. Tobacco smoking leads to a number of acute changes in the concentration of fatty acids, epinephrine, free glycerol, aldosterone, and cortisol. These changes occur within 1 hour of smoking one to five cigarettes. Moreover, within only 10 minutes of smoking a single cigarette there is an increase of glucose concentration by up to 10 mg/dL (0.56 mmol/L). This increase may persist for 1 hour.

Physical activity of varying duration and intensity may lead to substantial changes in the plasma composition, and the extent of this change depends on several factors, such as training status, fluid intake, electrolytes, and carbohydrates and even the ambient temperature, etc. For example, even a mild physical effort, like clenching a fist during venous blood sampling, can increase the concentration of potassium and should therefore be avoided. Intensive exercise is associated with transient elevations of cardiac biomarkers, markers of muscle damage, enhanced platelet aggregation, leukocytosis, elevation of tissue-plasminogen activator levels, and activation of the fibrinolytic system.

Some modifiable biological influence factors, such as diet, can be controlled by patient action, whereas some others (e.g., age) are noncontrollable. Proper standardization of controllable preanalytical variables will lead to the significant reduction of preanalytical variability.

To ensure standardization of patient preparation for blood sampling, the following general requirements should be applied to all blood tests in the fasting state:

1. Blood should be drawn preferably in the morning from 7 to 9 a.m.
2. Fasting should last for 12 hours, during which water consumption is permitted.
3. Alcohol should be avoided for 24 hours before blood sampling.
4. In the morning before blood sampling, patients should refrain from cigarette smoking and caffeine-containing drinks (tea, coffee, etc.).

Unmodifiable Influencing Factors

Various biological factors, known as **unmodifiable influencing factors**, lead to changes in analyte concentration, which are unavoidable (Table 3.1). These factors should be considered when interpreting laboratory results because their influence cannot be prevented by preanalytical standardization. Possible ways to address these factors are to partition reference intervals for age, race, gender, and month of pregnancy, and so on (see Chapter 5).

Interference Factors

Interference factors have the ability to alter the result of any analyte after the specimen has been collected, thus leading to falsely increased or decreased laboratory test results for that analyte. Their effect is assay dependent.

Interferences can be endogenous and exogenous. **Endogenous interferences** are biological constituents of the sample. They originate from the substances present in the patient sample whereas exogenous interferences are either present in the sample (drugs, herbal components, etc.) or are added to the sample

TABLE 3.1 Unavoidable Influences on Laboratory Results

Influence	Examples of Analyte Concentrations Changed	Remarks
Age	Alkaline phosphatase, LDL-cholesterol, hormones, creatinine	Provide age-dependent reference intervals
Race	Creatine kinase higher in black than in white males Granulocytes higher in white than in black Creatinine higher in black than in white	Provide race-specific reference intervals
Gender	Alanine aminotransferase, γ -GT, creatinine	Provide gender-specific reference intervals
Pregnancy	Triglycerides $\uparrow$, homocysteine $\downarrow$ during pregnancy	Document months of pregnancy with laboratory results
Altitude	CRP, hemoglobin $\uparrow$, transferrin $\downarrow$	Consider weeks of adaptation, when coming from or going to high altitude

CRP, C-reactive protein.

during or after sampling. **Exogenous interferences** relate to the effect of various substances added to the patient sample, such as separator gels, anticoagulants, surfactants, etc., all of which may cause significant interference.

Possible endogenous interference factors include:

1. Glucose
2. Paraproteins
3. Free hemoglobin (i.e., hemolysis)
4. Lipids (i.e., lipemia)
5. Bilirubin (i.e., icterus)

Possible exogenous interference factors include:

1. Drugs
2. Herbal components
3. Anticoagulants
4. Tube additives
5. Tube gels
6. Intravenous infusions

POINTS TO REMEMBER

Influencing and Interference Factors

- Influencing factors lead to changes in the quantity of the analyte in a method-independent way
- Influencing factors may be changeable (e.g., diet, time of the day) or unchangeable (e.g., gender, ethnicity, genetic background)
- The effect of influencing factors may be reduced through the standardization of preanalytical conditions
- Interferences are mechanisms and factors that lead to falsely increased or decreased results of laboratory tests
- Interference factors and their mechanisms differ with respect to the intended analyte and analytical method, and may be reduced or eliminated by selecting a more specific method

ENDOGENOUS INTERFERENCE FACTORS

Hemolysis

Definition and Background

Hemolysis is a process of membrane disruption of erythrocytes and other blood cells, accompanied by the subsequent release of cell components into the plasma and red coloration of the serum (or plasma) to various degrees, after centrifugation. Though hemoglobin is the most abundant protein in red blood cells, hemolysis is not necessarily always associated with the release of hemoglobin into the surrounding extracellular fluid. For example, if a blood sample is stored at a low temperature, low molecular intracellular components (e.g., electrolytes) diffuse from the cells, but hemoglobin will not. Furthermore, efflux of cell components due to cell lysis affects all blood cells (i.e., platelets and white blood cells) and not only erythrocytes. Therefore it is important to remember that red coloration of the serum or plasma can never accurately predict the concentration of analytes released from blood cell components.

Hemolysis is the most common preanalytical error and cause of sample rejection. Its frequency is up to 30% and accounts for almost 60% of unsuitable specimens. The frequency of hemolysis largely depends on the collection facility, the phlebotomy personnel, and the characteristics of the patient population. The highest frequency of hemolysis has been observed in samples from emergency departments, pediatric departments, and intensive care units, whereas hemolysis has proven to be the least frequent in outpatient phlebotomy centers where blood sampling is done by specialized laboratory staff. These differences are due to the level of knowledge and skills of the staff performing blood collection procedures.

There are two major sources of hemolysis: (1) *in vivo* and (2) *in vitro* hemolysis. **In vivo hemolysis** occurs within the body, before the blood has been drawn and is a result of a pathologic condition. Hemolysis *in vivo* may occur as a result of numerous biochemical (enzyme deficiencies, erythrocyte membrane defects, hemoglobinopathies), physical (prolonged marching, drumming, prosthetic heart valves), chemical (ethanol, drug overdose, toxins, snake venom), immunologic (autoantibodies) mechanisms, and infections (babesiosis, malaria). The most common causes of *in vivo* hemolysis are a reaction to incompatible transfusion and autoimmune hemolytic anemia.

In vivo hemolysis is not very common and accounts for only 3% of all hemolyzed samples. Laboratories should have a procedure in place for distinguishing *in vivo* and *in vitro* hemolysis. *In vivo* hemolysis should always be suspected when patient blood is hemolyzed over a longer period of time, after repeated blood sampling, even after special care has been taken to avoid hemolysis. Decreased concentration of haptoglobin in serum and free hemoglobin in urine are the most pronounced and specific laboratory signs of *in vivo* hemolysis. Haptoglobin is a protein that binds free hemoglobin in the circulation to prevent oxidative damage induced by hemoglobin. Once released from the erythrocyte into the plasma, hemoglobin forms complexes with haptoglobin, and those complexes are removed from the circulation by macrophages.

TABLE 3.2 Ratio Between Intracellular and Extracellular Concentration of Various Parameters in Red Cells

Analyte	Intracellular Concentration (Compared to Extracellular)
LDH (lactate dehydrogenase)	↑ 160×
Inorganic phosphate	↑ 100×
Potassium	↑ 40×
AST (aspartate aminotransferase)	↑ 40×
Folic acid	↑ 30×
ALT (alanine aminotransferase)	↑ 7×
Magnesium	↑ 3×

Note: The most pronounced effect of hemolysis is seen for LDH. LDH activity may be increased by >20% in mildly hemolyzed samples and as much as >350% in grossly hemolyzed samples.

In more pronounced cases of *in vivo* hemolysis, haptoglobin in serum can be undetectable (i.e., below the limit of detection), whereas its concentration in cases of *in vitro* hemolysis remains unchanged. When *in vivo* hemolysis is confirmed, the laboratory should not reject hemolyzed samples for analysis, since parameters in hemolyzed samples reflect the actual patient condition and are relevant for adequate patient care (diagnosis, therapy management, monitoring).

In vitro hemolysis occurs outside of the patient at various steps of the preanalytical phase (e.g., blood sampling, sample handling, delivery to the laboratory, and sample storage).

Mechanisms of Hemolysis Interference

Hemolysis is an endogenous interference that causes clinically relevant bias of patient results through several distinct mechanisms:

Spectrophotometric interference. Spectrophotometric interference of hemolysis occurs due to the ability of hemoglobin to absorb light at the following wavelengths: 415, 540, and 570 nm. This characteristic of hemoglobin causes optical interference, which can lead to either falsely increased or decreased concentrations of the measured parameters. The direction and degree of the interference largely depends on the analyte and the method.

Release of cell components into the sample. Some components are present in blood cells in concentrations that are several times higher than those in the extracellular space (i.e., plasma or serum). Table 3.2 shows some of the most pronounced differences between intracellular and extracellular concentrations in red cells.

From this it follows that there is a dramatic increase of the concentration of the listed analytes measured in hemolyzed plasma (or serum) due to the efflux of those substances from erythrocytes.

Since intracellular components may also escape from platelets during clotting, there is a marked difference in the potassium concentration between serum and plasma. The mean estimated difference in the concentration of potassium

in serum and plasma is 0.36 ± 0.18 mmol/L and this difference is positively associated with the platelet count. Plasma is therefore the recommended sample type for the accurate measurement of potassium.

Sample dilution. Some analytes, such as albumin, bilirubin, glucose, and sodium, are present in much higher concentrations in plasma than in blood cells. For those parameters hemolysis will cause a dilution effect and their concentrations will be lower in hemolyzed samples. The effect of sample dilution causes clinically significant bias only at a higher degree of hemolysis. For example, glucose is negatively affected by severe hemolysis (−8.3%) only when the concentration of free Hb is greater than 3 g/L.

Chemical interference. Various blood cell components may affect the analyte measurement procedure by directly or indirectly competing for molecules in the reagents, inhibiting indicator reactions or modifying the analyte by complexation, proteolysis, or precipitation. One such effect is caused by the enzyme, adenylate kinase, present in erythrocytes, as well as in platelets. When released from the cells during hemolysis, adenylate kinase may compete for ADP with creatine kinase in a creatine kinase assay if inhibitors are not supplied in the reaction mixture. Furthermore, hemoglobin released from erythrocytes during hemolysis may interfere with various assays through its pseudo-peroxidase activity. Pseudo-peroxidase activity of free hemoglobin released from erythrocytes interferes in the assay for measurement of bilirubin concentration through the inhibition of the formation of diazonium salt.

Hemolysis may cause a clinically significant interference on a wide range of analytes in immunochemistry assays. This interference is caused by modifying the reaction analytes (antigens and antibodies) by the proteolytic action of cathepsin E, the major proteolytic enzyme in mature erythrocytes. Proteolytic enzymes released from erythrocytes may mask or potentially enhance epitope recognition in various immunoassays. Interference caused by proteolytic activity may cause measurement bias of various degrees and directions, depending on the assay.

Lipemia

Lipemia is defined as turbidity of the sample visible to the naked eye. This turbidity is caused by light scattering due to the presence of large lipoprotein particles. The increase in concentration of lipoproteins in blood most commonly occurs due to postprandial triglyceride increase, parenteral lipid infusions, or some lipid disorders. Not all lipoproteins have equal contribution to the sample turbidity. The effect of lipoprotein particles on sample turbidity depends on the size of the particles. Chylomicrons and very-low-density lipoproteins (VLDLs), the largest lipoprotein particles in the circulation, have the greatest contribution to sample turbidity. To avoid postprandial lipemia, patients are requested to fast for 12 hours before blood sampling.

Mechanisms of Interference Caused by Lipemia

Lipemia is an important endogenous interference that may cause clinically relevant bias of patient results through the following mechanisms:

Spectrophotometric interference. Lipemia causes interference by light absorbance and light scattering. A lipemic sample absorbs light, decreasing the intensity of the light passing through the sample. This absorption occurs in the 300 to 700 nm wavelengths. Sample absorbance rises with the decreasing wavelengths and is maximal in the ultraviolet range. That is why many enzymatic methods in which the end product is measured at 340 nm are strongly affected by lipemia.

Lipemic samples also cause light scattering. Light scattering occurs in all directions and its intensity depends on the number and size of lipoprotein particles and the wavelength of measurement. For this reason, light scattering of lipoprotein particles causes significant interference with turbidimetry and nephelometry. In methods where the transmittance of light is inversely proportional with the concentration of the analyte, in the absence of the sample blank, sample turbidity causes positive bias. However, in some competitive assays where the transmittance of light is directly proportional to the concentration of the analyte, sample turbidity will cause negative bias.

Interference caused by the volume depletion effect. Plasma in healthy individuals in the fasting state consists of only a minor portion of lipids (<10% of the total plasma volume). The rest of the plasma is water. The increase in the concentration of lipoprotein particles leads to the increase of the plasma volume occupied by lipids. Particles that are not lipid soluble are displaced by the lipids to the water part of the plasma. Through this mechanism lipemia may lead to the false decrease of the concentration of the measured analyte, in all methods in which the concentration of respective analyte is measured in the total plasma volume (e.g., pseudo-hyponatremia if sodium is measured by flame photometry and indirect measurement using ion-selective electrodes, but not in direct potentiometry).

Interference caused by partitioning of the sample. Upon centrifugation of a lipemic sample, lipoproteins are not homogeneously distributed in the serum or plasma due to the lipid gradient. Water-soluble analytes are more concentrated in the lower layer of the plasma or serum, whereas lipids and lipid soluble analytes, such as drugs and some lipid-soluble hormones, are more concentrated in the top lipid-rich layer. This is especially important in automated chemistry analyzers with a fixed path length of the sample probe. Test results may differ for those analytes that are not evenly distributed between the lipid and water portions of the sample, depending on the part of the specimen from which the probe takes the sample for analysis.

Interference caused by physico-chemical mechanisms.

Excess lipoproteins in blood may interfere in electrophoretic and chromatographic methods by causing abnormal peaks. Elevated levels of triglycerides and lipoprotein particles may disturb the electrophoretic pattern as well as falsely increase the relative percentage of the prealbumin, albumin, and α_1 - and α_2 -globulin regions. Moreover, lipemia may affect some immunochemistry assays by masking the binding sites on antigens and antibodies, and thus physically interfere with antigen-antibody binding.

Removal of Lipids from the Sample

Unlike hemolysis, the interference caused by lipemia can be fully eliminated or at least reduced, by removing the excess lipids from the sample. Methods for lipid removal include ultracentrifugation, high-speed centrifugation, and some lipid clearing agents.

Ultracentrifugation is the recommended method for the removal of the excess of lipids in the sample. Ultracentrifuges use the centrifugation force of almost 200,000 g and are very effective in clearing lipemic sera by separating lipids, especially chylomicrons (top layer), from the aqueous part (lower layer) of the sample. After centrifugation, the infranatant (lower part of the sample) can be analyzed. It should be kept in mind that by removing the upper lipid layer one also removes lipid soluble analytes such as drugs and hormones. Results reported from ultracentrifuged samples or samples from which lipids have been removed in any other way, should be appropriately annotated to ensure clinicians are aware that the sample has been manipulated to obtain the reported results.

In laboratories where ultracentrifuge is not available, high-speed centrifugation using the microcentrifuge with a maximum centrifugation speed of up to 20,000 g for 15 minutes at room temperature may serve as an acceptable alternative.

Lipid clearing agents are widely used in many laboratories due to their low cost, convenience, and ease of use. Those agents (cyclodextrin, polyethylene glycol, dextran sulfate, hexane, and others) may vary in their ability to extract lipids from a lipemic sample, and may lead to reduction of a significant amount of protein from the sample. It is therefore very important for laboratories to verify the performance of such reagents before their routine use.

Icterus

The normal concentration of bilirubin in human plasma (or serum) is up to 20 $\mu\text{mol/L}$. A change in the color of the serum (or plasma) becomes detectable when bilirubin concentration exceeds 34 $\mu\text{mol/L}$. Bilirubin concentrations above 100 $\mu\text{mol/L}$ are clinically defined as **icterus**. Bilirubin interferes with numerous chemistry tests, such as enzymes (alanine aminotransferase, alkaline phosphatase, creatine kinase, lipase), electrolytes, metabolites (urea, creatinine, glucose), lipids (cholesterol, triglycerides), proteins (albumin, total proteins, immunoglobulin [Ig]-G), hormones (estradiol, beta-human chorionic gonadotropin [β -hCG], free T3), and even some drugs (gentamicin, phenobarbital, theophylline, tobramycin). As is the case for hemolysis and lipemia, interference caused by bilirubin differs between instruments and assays.

Unfortunately, there is not much that can be done by the laboratory to remove or minimize the effect of icteric interference. Possible options are diluting the sample (possible only for analytes present at high enough concentrations in the blood) and testing the requested analytes with a different method or on a different instrument for which icterus does not cause clinically significant interference.

Mechanisms of Interference Caused by Icterus

Icterus interferes through two mechanisms: spectrophotometric interference and by interfering with chemical reaction. It is important to recognize that both mechanisms may occur simultaneously in one sample.

Bilirubin causes spectrophotometric interference due to its ability to absorb light in the wide range of wavelengths between 400 and 540 nm.

Chemical interference of bilirubin is exerted through its interaction with various components in the blood. For example, bilirubin produces negative bias on assays that involve H_2O_2 as an intermediate reaction (e.g., cholesterol, glucose, uric acid, triglycerides).

Detection of Hemolysis, Lipemia, and Icterus

Hemolysis becomes visible at the concentration of 0.3 to 0.5 g/L of free hemoglobin and the intensity of the red color of the serum or plasma further increases with the increase in concentration of free serum hemoglobin (Fig. 3.1A). Lipemia causes sample turbidity, which approximately corresponds to the concentration of serum triglycerides (see Fig. 3.1B). Increased concentrations of serum bilirubin lead to yellow-to-orange coloration of the serum, and the change of the color correlates with the increasing concentration of the bilirubin in serum (see Fig. 3.1C).

Detection of the degree of hemolysis, icterus, and lipemia by visual inspection is highly unreliable and should be replaced with automated detection. Most high-throughput chemistry analyzers currently available on the market have the ability to detect serum indices by the use of semi-quantitative, spectrophotometric measurement, and grading the interfering substances into categories. The serum index is automatically reported for every sample and can be used to determine the degree of interference and its effect on the requested parameters. Such systems are highly reproducible and provide an objective and standardized way to screen for common interferences and manage specimen rejection via built-in rules in analyzer software.

Although the information about serum indices and their cut-offs for tested analytes are provided by the manufacturers of in vitro diagnostic systems and reagents, their claims are often not complete, accurate, and reproducible. It is therefore good practice for a laboratory to perform its own verification of serum indices. Alternatively, laboratories may rely on the evidence from the literature, if available and of adequate quality.

As for all other laboratory methods, analytical quality of serum indices should be continuously monitored by using appropriate internal quality control (IQC) and through participation in an external quality assessment program (EQA). IQC material for serum indices has been recently made available on the market by several manufacturers.

EXOGENOUS INTERFERENCE FACTORS

The effects of exogenous interfering substances are difficult to identify. They are introduced into the sample in different ways; for example, through therapy (drugs, natural preparations for self-medication, or supportive therapy), diagnostic

Fig. 3.1 (A) Hemolysis—the intensity of the red color of the serum and corresponding concentrations of free serum hemoglobin. (B) Lipemia—the degree of turbidity and corresponding concentrations of triglycerides. (C) Icterus—the intensity of the yellow color of the serum and corresponding concentrations of bilirubin. *Concentration of Intralipid; **concentration of triglycerides. (Standard color scales; Courtesy Clinical Institute of Chemistry, University Hospital Center “Sestre Milosrdnice,” Zagreb, Croatia.)

procedures (contrast media), by accidental exposures and poisonings (with drugs, herbs, household chemicals, etc.), and through contamination of the sample during sample handling (from rubber tube stoppers, lubricants, anticoagulants, or surfactants) or sample analysis (antibiotics used for reagent and buffer stability).

POINTS TO REMEMBER

Hemolysis, Lipemia, Icterus

- Visual assessment of the degree of hemolysis, lipemia, and icterus is not reliable and leads to errors.
- Hemolysis is the most common preanalytical error and most common cause of sample rejection.
- Hemolysis may cause clinically relevant bias through spectrophotometric and chemical interference, sample dilution, and the release of cell components into the sample.
- Lipemia causes interference by spectrophotometric interference (light absorbance and light scattering), by the volume depletion effect, by partitioning of the sample, and by physico-chemical mechanisms (e.g., disturbance of the electrophoretic pattern).
- Laboratories should verify the performance of lipid removal reagents before their routine use, since they may not be appropriate for a wide range of analytes due to their low recovery.
- Different forms of bilirubin cause varying degrees of interference with different laboratory methods, and the same forms of bilirubin act differently with the same assays on different instruments.

SPECIFIC CONSIDERATIONS

Besides the general aspects of preanalytical quality (i.e., patient and sample identification, controllable and uncontrollable variables), some specific aspects related to urine, saliva, and blood gas testing are of particular relevance to laboratory medicine. The following sections deal with the preanalytical aspects of sample types other than serum or plasma, and other types of testing that deserve special preanalytical considerations.

Influences and Interferences in Urine Testing

Some of the most important preanalytical issues in the analysis of urine are patient preparation, choice of urine type, type of collection vessel, sample stability during transport and storage, sample homogeneity, and sample contamination. These aspects are covered below.

Types of Urine

Not every urine sample is fit for the purpose of every type of laboratory testing. The possible types of urine sample and their intended use are described in [Table 3.3](#).

When collecting urine specimens, in order to prevent contamination with bacteria that normally reside on the skin, hygiene of the hands and genitalia is essential. Hands should be washed with soap, thoroughly rinsed with water, and dried. Not only proper washing with soap, but also thorough rinsing is extremely important, as baby soaps are known

TABLE 3.3 Urine Specimens and Their Diagnostic Use

Urine Type	Use
First morning urine	Urine sediment, test strip
Second morning urine	Proteins, urinalysis
Timed urine (6–24 h)	Hormones, drugs, electrolytes
First void urine	Chlamydia
Midstream urine	Urinalysis, microbiologic examination
Urine obtained through a catheter or sterile suprapubic aspiration	Exclusion and confirmation of urinary tract infection

to cause significant interference with tetrahydrocannabinol (THC) immunoassays. To prevent sample contamination by skin microorganisms, it is very important not to touch the inner surface of the cap and the container during collection. Urine should be collected while holding the skin folds (labia) apart (females) or retracting the foreskin (uncircumcised men) during voiding.

First morning urine (also called overnight or early morning specimen) is collected immediately after arising from an overnight sleep. Exceptionally, in patients suffering from insomnia or in night-shift workers, other 8-hour periods may also be used for the purpose of first morning urine collection. It is important that the patient's bladder is emptied immediately before going to sleep and that any amount of urine voided during the night is also collected and pooled together with the first voided morning specimen.

Timed urine specimens are collected at a specified time or in relation to some activity (e.g., before a meal, after a meal, before therapy, before exercise, and so on) during a 24-hour period. The exact time of the collection should always be reported with a test report.

First void urine comprises the first portion of the urine (usually first 15 to 50 mL) passed at any time of the day. It is collected after a patient has not urinated for at least 1 to 2 hours. The exact time depends on the sensitivity of the actual test method and is usually designated on the method insert sheet.

Midstream urine (also called clean catch specimen) is a specimen collected during the middle of a urine flow, after the urinary opening has been carefully cleaned. The first amount of urine should be passed into the toilet instead of the container. This will prevent contamination with skin, vaginal or urethral cells, and bacteria. The mid-portion of the urine is collected and once the container is filled, the rest of urine is voided into the toilet until the bladder is empty.

Suprapubic aspiration and catheterization are procedures usually applied for bacteriologic studies to obtain uncontaminated urine. A suprapubic specimen is collected by aspirating urine from the distended bladder through the abdominal wall, while catheterization enters the bladder through the urethra. Both collection methods use the sterile technique.

The ideal container for any urine specimen is a wide-mouthed bottle of appropriate size. Containers should be clean, leak proof, particle-free, and preferably made of a clear,

disposable material that is inert with regard to urinary constituents. If urine is to be transported, the container used during transportation should have a secure closure to prevent leakage of the contents during transportation. If the urine is to be analyzed bacteriologically, containers have to be sterile.

For pediatric and newborn patients, urine specimen collection bags with hypoallergenic skin adhesive should be used. First, the pubic and perineal areas should be cleaned with soap and water. Then, the adhesive strip should be pressed all around the vulva or the bag fixed over the penis and the flaps pressed to the perineum.

Transport and Storage of Sample

Since some urine parameters have limited stability in unreserved urine, temperature and time conditions during transport and storage of urine are very important to ensure adequate sample quality. Urine samples may be stored for up to 1 hour at room temperature and up to 4 hours if refrigerated without significant variation in the results of the physical, chemical, and morphologic analysis of particles. Chemical constituents in urine (for test strip analysis) are stable for 24 hours if urine has been kept at +4°C.

POINTS TO REMEMBER

Urine

- The contamination rate is much lower in urine specimens collected after proper hand and genital hygiene.
- Laboratories should provide instructions to patients about reasons for urine collection, how to prepare for urine sampling (e.g., effects of diet and fluid intake, diuresis, exercise, and other interferents), and how to properly collect urine.
- Stability of different analytes in urine is limited and decreases during prolonged storage and at higher temperatures.
- Preservatives like ethanol, polyethylene glycol, sodium fluoride, mercuric chloride, boric acid, and formaldehyde- and formate-based solutions may enhance the stability of urine particles.
- The addition of urine stabilizers inhibits the bacterial growth, metabolic processes, and degradation of urine analytes and particles.

Saliva

Saliva is produced by *major* salivary glands (parotid, submandibular, and sublingual glands) and by oral secretion of the mucus by hundreds of *minor* salivary glands. The primary function of saliva is to provide oral protection by lubrication, digestion, and an immune response. Saliva is an attractive alternative to blood because it is collected noninvasively. As a diagnostic sample, saliva offers many advantages as well as some challenges ([Box 3.1](#)).

Types of Saliva Samples

The easiest way to collect saliva is to collect whole oral fluid (whole saliva). Whole saliva is representative of the oral milieu. However, depending on the intended aim of the

BOX 3.1 Advantages and Challenges of Using Saliva as a Diagnostic Specimen

Advantages

- Rapid and easy collection by minimally trained individuals
- Sampling can be done by patients, at home, out of hospital
- Multiple sample collection is possible
- Procedure safe and painless for the patient
- Convenient in children, psychiatric patients, and stress research
- Availability
- Low cost associated with sampling (skilled staff not required)
- Convenient method for population screening programs
- Low risk of infections associated with sampling

Challenges

- Low analyte concentration
- Some analytes may be affected by circadian cycle
- Questionable recovery for some analytes
- Risk of contamination during collection
- Difficult sampling and low patient compliance (in small children)

sample collection and analyte to be tested, some other sample types are also possible. Various sampling techniques and devices are available. Whereas collection of whole oral fluid is an easy procedure, other sampling methods are more complicated; they require trained staff and are not commonly used.

Whole saliva may be collected as unstimulated (mostly produced by the submandibular glands) and stimulated (originating predominantly from the parotid glands) samples. Stimulation of saliva is obtained by oral movements (yawning, chewing paraffin or gum), or using a cotton roll soaked with citric acid. It has to be noted that stimulated and unstimulated saliva are of different origin (produced by different salivary glands) and composition (concentration of some analytes may vary), and thus are not equally suitable for all assays.

Several commercially available devices may be used for collection of saliva. **Unstimulated whole saliva** can be collected by:

- Passive drooling into the plastic vial
- Spitting into the collector vial

Passive drooling is considered by many to be the gold standard collection method for many analytes, as it enables collection of a representative portion of saliva present in the oral cavity. Moreover, passive drooling is preferred over spitting, since saliva collected by spitting is more likely to be contaminated with bacteria.

Stimulated saliva may be obtained by adsorbing saliva by cotton rolls, cotton swabs, or filter paper. Cotton is not an ideal collection material, not only due to its unpleasant texture, but also because it may induce some variations in salivary immunoassays (some analytes are difficult to elute from cotton). To address this

problem, some synthetic materials have been made available, such as inert polymers, polystyrene, rayon, and polyester. It must be emphasized that the composition of saliva collected by the use of various adsorbent devices may differ from the whole saliva, as adsorbent devices mostly collect localized saliva.

Patient Preparation for Saliva Sampling

The laboratory is responsible for providing information to the patient about the purpose of saliva collection, as well as how to prepare for collection, and how to collect saliva. To avoid sample contamination, it is recommended to wear gloves during saliva collection. Below are some important measures aimed to minimize errors and ensure high-quality saliva samples:

- If not otherwise decided by the requesting physician, saliva should be collected in the morning, preferably in the fasting state (the exact time of collection is important, as some analytes may have diurnal variations)
- The patient should wash his/her face with water and soap and rinse it thoroughly to avoid contamination with facial creams and lotions
- The patient should not consume alcohol 12 hours before the collection
- The patient should not brush or floss his or her teeth at least 30 minutes before the collection
- The patient should not have any dental work done 2 days before the collection (dental bleeding may affect the test results)
- The patient should not ingest any food and drinks (except water) within 30 minutes before the collection
- The patient should not chew gum for at least 30 minutes before the collection
- Before collection, the patient should rinse his or her mouth with water to remove some food remnants. To avoid sample dilution with water, the sample should be collected 10 to 15 minutes after rinsing the mouth.

Any sample visibly contaminated with blood or food remnants should be rejected for analysis, and sample re-collection should be requested.

Preanalytical Aspects of Arterial Blood Gas Testing

Blood sampling for assessing the oxygenation status of the patient or acid-base balance should be done when a patient is in a stable, resting state, to ensure that test results reflect the actual condition of the patient. Furthermore, the exact time of the blood collection should always be recorded and reported with a test result. Any deviation from the steady state should be noted as a comment and accompany the test report in order to allow proper interpretation of the results and appropriate patient management.

Relevant patient condition determinants (at the time of blood collection) are:

- Patient status (resting, exercising, crying, anxious)
- Ventilatory setting (spontaneous breathing or assisted mechanical ventilation)
- Mode of oxygen delivery (fraction of inspired oxygen [FiO₂] through nasal cannula or Venturi mask)

- Respiratory rate (hyperventilation, hypoventilation)
- Body temperature

If a patient's condition is changing, sufficient time should be allowed for the patient to stabilize. If there has been any change in the patient ventilatory setting or the mode of oxygen delivery, the patient should also be left in the resting state to stabilize. For patients without pulmonary disease, a period of 3 to 5 minutes is usually enough to stabilize. However, in patients with pulmonary disease, this period is significantly longer. For most patients, 20 to 30 minutes is adequate time to reach a stable state following ventilatory changes.

Arterial blood collected under anaerobic conditions and anticoagulated with lyophilized balanced Li-heparin is the ideal sample type for an accurate evaluation of the gas exchange function of the lungs (pO_2 and pCO_2). If arterial blood is not available (e.g., neonates, small children, patients with burns), and during medical transport and prehospital critical care, a capillary sample is an acceptable alternative. Capillary blood sampling is not recommended in patients with circulatory shock, poorly perfused (cyanotic), infected, inflamed, swollen, or edematous tissues. For more details on blood gas analysis and sample collection and processing, see Chapters 6 and 24.

Hemostasis Testing

Some specific considerations related to hemostasis testing are associated with the type of anticoagulant, sampling technique (fasting state, length of the venous stasis, order of draw, sampling from a catheter), sample handling (centrifugation), transport, and storage prior to analysis.

Samples for hemostasis testing should be anticoagulated with 3.2% sodium citrate, although 3.8% may also be acceptable. It is important that the same concentration of sodium citrate is used within the laboratory, since clotting times may be longer in 3.8% than in 3.2% sodium citrate.

The mixing of samples is extremely important for adequate sample coagulation. Samples must be promptly mixed to avoid in vitro clot formation. Tubes should be mixed by gentle inversion (at 180 degrees) several times. For proper mixing, instructions from the tube manufacturer should be followed. Vigorous mixing and shaking the tubes is discouraged, as it may lead to sample hemolysis, plus the activation of platelets and coagulation factors, resulting in false shortening of clotting times and even the possible false increasing of clotting factor activity. The transport of samples by pneumatic tubes is still under discussion. While some claim that pneumatic tube transport is acceptable for routine hematology and coagulation testing, others argue that it is not appropriate for platelet aggregation studies. It is therefore recommended that each institution verifies the acceptability of their tube transport systems by comparing paired samples for differences.

Samples with visible clots should not be accepted for hemostasis testing. To prevent clot formation during blood sampling, handling, and transport, the following situations should be avoided:

- Blood flow (during blood sampling) too slow
- Collecting the sample into a syringe and then transferring it into a citrated tube

- Tubes underfilled
- Prolonged use of tourniquet (longer than 1 minute)
- Considerable manipulation of the vein by the needle
- Incomplete mixing

Clot formation induces the activation of platelets and clotting factors and the release of granules from the platelets, and it may cause false results in coagulation assays. It is very important to point out that even small clots that are invisible to the human eye may significantly impact coagulation assays.

The required blood to anticoagulant ratio is 9:1 and it is therefore very important that tubes for coagulation assays are filled to the mark noted on the tube. Acceptable deviation is a maximum 10% of the total volume; overfilling or underfilling the designated volume is strictly discouraged as this can introduce bias in test results. Laboratories should have preanalytical procedures in place for the rejection of over- or underfilled tubes. Other anticoagulants (e.g., ethylenediaminetetraacetic acid [EDTA] or heparin) are not acceptable for hemostasis testing, since they lead to erroneous results and cause clinically significant errors.

A standardized order of draw has been recommended, with the coagulation tube as the first tube. Although a "discard" tube before the coagulation tube has long been recommended, more recent evidence suggests that it may not be necessary. If intravenous catheter systems are used for blood sampling, 5 to 6 times the dead space (priming) volume of the catheter should be discarded prior to blood sampling.

Following collection, citrated samples should ideally be transported to the laboratory immediately and at room temperature, but no later than within 1 hour of blood draw. All coagulation assays should be performed in fresh samples. Blood samples for coagulation testing must be kept at room temperature (20 to 25°C) until analysis. Storage at a lower temperature, or on ice, and sample freezing are discouraged as some coagulation factors are activated by cold.

Whole blood coagulation assays should be performed within 4 hours after blood sampling. For platelet function assays, samples should rest (at room temperature) for 30 minutes before analysis. Platelet function assays require the careful preparation of platelet-rich plasma by centrifugation of the blood at 200 to 250 g for 10 minutes without application of a centrifuge brake. To generate platelet-poor plasma, centrifugation is normally performed at 1500 g at room temperature for 10 to 15 minutes. Higher speed with a shorter centrifugation time is not recommended, as this may induce hemolysis and activation of platelets.

Hematology

EDTA is the anticoagulant of choice for hematology testing given its efficacy of preserving cellular morphology. Due to its higher solubility, lower osmotic effect, and best overall performance, the International Council for Standardization in Haematology (ICSH) recommends dipotassium EDTA salt as the anticoagulant of choice for hematology testing.

Blood tubes should be filled to $\pm 10\%$ of the stated draw volume. In underfilled EDTA tubes, cell count and hematocrit might be falsely decreased due to the excess EDTA. In

overfilled tubes, clot formation and platelet clumping is likely to occur, due to difficulty of appropriate mixing.

In some individuals EDTA may cause pseudothrombocytopenia (i.e., platelet clumping or platelet satellitism [platelet adhering to neutrophils]) and subsequently inaccurate platelet results. Since most cell counters are not able to identify this preanalytical problem, platelets are thus counted as white blood cells, resulting in spurious leukocytosis and false thrombocytopenia. EDTA-induced pseudothrombocytopenia has so far been observed in healthy and diseased individuals, and is not related to gender and age. The hypothesized mechanism in pseudothrombocytopenia involves IgM autoantibodies, directed against platelet IIb/IIIa fibrinogen receptors. This is further supported by the fact that platelets from patients with Glanzmann thrombasthenia (in which platelets have either defective or low levels of glycoprotein IIb/IIIa) do not react with autoantibodies from pseudothrombocytopenic patients.

EDTA anticoagulated blood should be stored at room temperature and analyzed within 6 hours of collection. Stability of hematologic parameters may differ depending on the parameter that is being measured, the instrument type, the transport, and the storage conditions. Therefore, on some occasions, a shorter time is necessary to ensure accurate and reliable results, whereas some parameters show excellent stability even over much longer time intervals. Some parameters are very stable (hemoglobin and red blood cells), while some others are not (reticulocytes, mean cell volume, and hematocrit). The stability of hematologic parameters is improved if samples are kept at 4°C. The following are the data provided by the ICSH on the stability of some hematology parameters:

- Hemoglobin concentration and red blood cell count are stable up to 72 hours, if blood is kept at 4°C
- Platelet and reticulocyte count are stable for 24 to 72 hours, if blood is stored at 4°C
- White blood cell count with automated differential count is stable for at least 24 hours, if blood is kept at 4°C, and up to 6 hours if stored at room temperature
- Peripheral blood smear should be made from blood stored no longer than 1 hour at room temperature (18°C to 25°C)

Since stability may vary depending on the instrument, it is the responsibility of the individual laboratory to verify the stability of hematologic parameters on the instruments used in their laboratory.

Antibodies may affect the cell count of erythrocytes, leukocytes, and platelets. The following antibodies are known to interfere with hematologic analytes:

- Cold agglutinins (erythrocyte specific)
- Cryoglobulins
- EDTA-dependent antibodies with thrombocyte and leukocyte specificity

Cold Agglutinins

Cold agglutinins are monoclonal or polyclonal antibodies specific for erythrocyte surface carbohydrate antigens, which bind to the erythrocyte surface at 0°C to 4°C. Binding of these antibodies causes agglutination of erythrocytes, induces

complement activation and hemolysis, and impairs peripheral circulation. Some rare cases of cold agglutinins toward platelets have also been described, causing pseudothrombocytopenia independent of EDTA.

Cold agglutinins, if undetected, may cause diagnostic confusion and lead to subsequent extensive diagnostic workup as well as wrong and unnecessary therapy, risking patient safety and increasing healthcare costs. It is therefore very important to recognize cold agglutinins promptly.

Cold agglutinins should be suspected if the following anomalies are observed:

- Red blood cell count too low (in the presence of normal hemoglobin concentration)
- Significantly increased mean corpuscular volume (MCV) values
- Significantly low values of calculated hematocrit in samples with too high mean corpuscular hemoglobin (MCH) and MCH concentration (MCHC) values without any obvious explanation
- Falsely elevated white blood cell and platelet count

White blood cell and platelet counts may be falsely elevated because agglutinates, depending on their size, are either counted in the leukocyte or platelet channel. The blood smear may also show agglutination of erythrocytes. For adequate analysis of samples in which cold agglutinins are suspected, it is essential to warm up the EDTA blood sample at 37°C and analyze it immediately afterwards. This anomaly will appear again if a sample is kept at 4°C and analyzed cold.

Cryoglobulins

Cryoglobulins are immunoglobulins with temperature-dependent solubility that precipitate at temperatures below 37°C. Cryoglobulins are often associated with infections, autoimmune disorders, and malignancies, and cause organ damage through immune-mediated mechanisms and vascular damage due to increased viscosity of the blood. The precipitation of cryoglobulins depends on the immunoglobulin class to which they belong. Also, precipitation is absent at pH less than 5.0 or more than 8.0.

In samples kept at room temperature, cryoglobulins tend to form globular or cylindrical precipitates, which are then counted by automated hematologic analyzers as cells, thus affecting hematologic laboratory tests and leading to false leukocytosis (pseudoleukocytosis), or false thrombocytosis (pseudothrombocytosis). The degree of pseudoleukocytosis and pseudothrombocytosis depends on the time of exposure, temperature, cryoglobulin concentration, and the interaction of cryoglobulins with other plasma proteins. The following indices may point to the presence of cryoglobulins:

- Very different cell counts in different investigations
- Blue sediments in differential count samples
- In a sample warmed up to 37°C, significantly lower cell counts are measured

As is the case with cold agglutinins, for adequate analysis of samples in which cryoglobulins are suspected, blood sample should be kept warm at 37°C and analyzed immediately afterward.

REVIEW QUESTIONS

- Which of the following statements best describes the way interference factors may be reduced or eliminated?
 - By standardizing the preanalytical conditions
 - By providing proper instructions to the patients on how to prepare for blood sampling
 - By selecting a more specific method
 - By selecting the appropriate sampling procedure
 - By maintaining the analytical variability (method CV_A) to a minimum
- Spectrophotometric interference of hemolysis occurs due to the ability of hemoglobin to absorb light at which wavelengths?
 - 400, 500, and 600 nm
 - 550 and 570 nm
 - 540 and 600 nm
 - 415 and 540 nm
 - 415, 540, and 570 nm
- Recommended sample for the accurate measurement of potassium is which of the following?
 - Plasma
 - Serum
 - Whole blood
 - Capillary blood
 - Arterial blood
- Which of the following statements is true for lipid testing and testing for lipid-soluble drugs and hormones?
 - Testing should always be done in a delipidated sample.
 - Testing should always be done on the native sample before delipidation.
 - Delipidation does not affect the concentration of lipids and lipid-soluble drugs.
 - The most suitable delipidation method is ultracentrifugation.
 - The most suitable delipidation method is lipid removal using the lipid clearing agents.
- Major sources of exogenous interferences are described below, EXCEPT?
 - Prescribed medications
 - Supportive medical therapy like parenteral emulsions, contrast media agents, or infusion solutions
 - Dietary supplements
 - Accidental exposure and poisoning
 - In vivo hemolysis
- According to the International Council for Standardization in Haematology, the anticoagulant of choice for hematology testing is:
 - dipotassium EDTA.
 - tripotassium EDTA.
 - disodium EDTA.
 - 3.8% sodium citrate.
 - 3.2% sodium citrate.

Biological Variation

Sverre Sandberg, Thomas Røraas, Aasne K. Aarsand, Callum G. Fraser

OBJECTIVES

1. Explain the nature of biological variation and how estimates of within- and between-subject biological variation can be generated.
2. Explain how estimates of biological variation can be applied in laboratory and clinical practice.
3. Design biological variation studies for measurands in clinical chemistry.
4. State the formula for reference change value calculations and illustrate its use with examples.
5. Describe the various models for setting analytical performance specifications, and critically assess the advantages and disadvantages of each model.

KEY WORDS AND DEFINITIONS

Analytical performance specifications The analytical performance needed to fulfill certain requirements—often given as numerical values.

Analytical variation (CV_A) Variation of the concentration of a measurand in a sample measured several times with the same measurement procedure (imprecision)

Between-subject variation (CV_G) The variation in the concentration of a measurand among the homeostatic set points of different individuals.

Biological variation Variation in the concentration of a measurand in the body not caused by disease (or analytical variation).

Critical difference The change in a result that, with a certain probability, makes it significantly different from a previous result. The preferred synonym is reference change value (RCV; see later).

Index of individuality (II) The distributions of measured values from samples from healthy individuals in relation to the population-based reference interval.

$$II = (CV_A^2 + CV_I^2)^{1/2} / CV_G$$

Reference change value The change in a result that, with a certain probability, makes it significantly different from a previous result.

Within-subject variation (CV_I) The variation in the concentration of a measurand within each individual around their own homeostatic set point.

There are many sources of variation in numerical results generated in laboratory medicine. Although some measurands have biological variations over the span of life, and others have predictable cyclical variation, most measurands have random variation around homeostatic set points, which differ between individuals. Knowledge of the generation and application of data on within-subject and between-subject biological variation is essential for the correct interpretation of results.

NATURE OF BIOLOGICAL VARIATION

There are many sources of variation that contribute to the uncertainty of any result generated in laboratory medicine. **Biological variation** is one of the most important and should be taken into account when results are interpreted.

There are various types of biological variation. The concentration or activity of some measurands changes over the span of life—some slowly and some more quickly, particularly at times of physiological change, such as the neonatal period, childhood, puberty, the menopause, and old age. The concentration or activity of measurands can also differ between men and women. This variation is taken care of by the creation of age- and/or sex-stratified (partitioned) reference intervals when these are needed. In addition, many measurands have predictable cyclical rhythms in their concentrations. These can be daily, monthly, or seasonal in nature. The major ramifications for interpretation are that reference intervals cannot be generated for every point during these cycles. Therefore specimen collection must be performed at appropriate times.

TABLE 4.1 Serum Sodium Activity (mmol/L) in Four Specimens Collected at Daily Intervals from Each of a Cohort of Four Individuals

Sodium	Day 1	Day 2	Day 3	Day 4
Individual 1	137	139	136	138
Individual 2	144	146	145	144
Individual 3	141	143	142	140
Individual 4	139	138	141	140

The most important type of biological variation is random biological variation. As an example, four specimens were taken from four individuals at daily intervals, and serum sodium activity (reference interval: 135 to 147 mmol/L) was examined (Table 4.1). It is evident that the results for each individual vary from day to day; this is due to three sources of variation, namely, preanalytical, analytical, and within-subject biological variations. In addition, each individual has a different average serum sodium activity, which is termed the homeostatic set point. The variation among the homeostatic set points of individuals is the **between-subject variation**, whereas the variation within each individual around their own homeostatic set point is the **within-subject variation**. The individuality of a measurand and the use of conventional population-based reference intervals are determined by comparison of the within-subject and between-subject biological variations. Within-subject biological variation and analytical imprecision can be used to create **reference change values** (RCVs), sometimes called **critical differences**, to assess the statistical significance of changes in serial results from an individual or the probability that any change seen is significant. Analytical performance specifications (APS) for imprecision, bias, allowable total error, measurement uncertainty, and other characteristics also can be created using within-subject and between-subject variation. The generation and subsequent application of numerical data on the components of biological variation are crucial facets of laboratory medicine and are described in detail in this chapter.

The range of terms and the variety of symbols used to define the components of biological variation have grown with the increasing body of literature. The internationally agreed terms and symbols used throughout this chapter are:

- CV_I : within-subject biological variation (variation within a single individual estimated as a pooled variation from a [homogeneous] group of individuals)
- CV_G : between-subject biological variation (variation between the central tendencies of a group of individuals)
- CV_A : **analytical variation** (analytical imprecision)

GENERATION OF DATA ON COMPONENTS OF BIOLOGICAL VARIATION

Production of data on biological variation is similar to derivation of population-based reference intervals except that, instead of one specimen being taken from many reference individuals, the specimens are taken from a smaller cohort.

In general terms, the traditional approach recommends that numerical estimates of CV_A and both CV_I and CV_G components of biological variation should be generated using the following experimental approach:

- Select a group of reference individuals (usually apparently healthy volunteers)
- Take a set of specimens from each of the individuals at regular time intervals while minimizing all sources of pre-analytical variation in preparation of the subjects for specimen collection
- Transport specimens in a standardized way and store aliquots under controlled conditions until ready for analysis
- Undertake the analyses in duplicate while minimizing analytical sources of variation
- Remove statistical outliers and confirm that all results from the individuals are homogeneous
- Dissect out the CV_A , CV_I , and CV_G components using nested analysis of variance (ANOVA) (or alternatively general linear models or generalized linear models)

Design of Studies

The preceding general design has been widely used and is very suitable for those measurands that have low CV_I and tight homeostatic control, but it is somewhat simplistic for many reasons. The measurand may be unstable, and analyses would need to be performed soon after the collection of specimens (e.g., for some hematologic measurands, such as mean cell volume, and erythrocyte and leukocyte counts per volume). In this case, to obtain the necessary statistically unfounded estimate(s) of CV_I , quality control materials have to be analyzed during each run to ascertain that variation, due to random or systematic error in the procedure between each analysis, is not introduced. Using this strategy, the quality control material should preferentially be commutable; meaning that the variations of the analyses of the individual samples and the quality control materials are comparable. Furthermore, it must be ensured that the concentrations or activities of the quality control materials are similar to those of the samples from the subjects studied because CV_A often varies with concentration or activity.

Estimates in laboratory medicine are usually accompanied by confidence intervals (CIs); unfortunately, this has rarely been delivered in most published reports to date that provide estimates of the components of biological variation. CIs are essential for appraising the results and comparing results between studies. It has been found that the reliability of an estimate for CV_I is greatly influenced by the study design and by the ratio between CV_A and CV_I . For a limited number of measurements, it is preferable to have a relatively high number of specimens from each individual. On the other hand, if the influence of factors, such as age and sex, on within-subject biological variation is under study, it is important that an adequate number of individuals are included in each sub-group to detect clinically important differences. If the CV_A is high compared to the CV_I , either the total number of specimens or the number of replicate analyses should be increased.

Fig. 4.1 Means and extreme values for serum creatinine in 27 older adults. Note: 100 $\mu\text{mol/L}$ = 1.13 mg/dL. (From Fraser, C. G. [2004]. Inherent biological variation and reference values. *Clinical Chemistry and Laboratory Medicine*, 42, 758–764.)

Methods for Analysis

Steady State, Outliers, and Homogeneity

The currently accepted best method for sample collection and data analysis is detailed by Fraser and Harris, whereby duplicate analyses are performed on samples from a cohort of individuals. However, before any components of variation are estimated, it is important (1) to verify that the individuals are in a steady state; (2) to exclude outliers in the data set; and (3) to assess whether the individuals have a homogeneous within-subject CV_I .

Steady state. The calculation of biological variation data assumes that the individuals assessed are in a “steady state,” that is, the homeostatic set points do not change during the time span of the study. If this is not the case, data should be transformed to a “steady state,” for example, by correcting for trends using regression analysis.

Outliers. The assessment of outliers is important because such aberrant values will lead to erroneous estimates of the components of biological variation. It is important that this assessment is done using the same measure of variability that is estimated; that is, if coefficients of variation (CVs) are estimated, which is usually the case, all the calculations should be performed using CVs. This can be achieved by normalizing data, for example, through $\log_e$ -transformation. After transformation, outlier assessments are performed at three levels: (1) between duplicates or replicates, (2) between samples within an individual, and (3) between individuals. For levels 1 and 2, typically Cochran’s test is used, but applied to the CV^2 and not to standard deviation (SD)². Failure to remove outliers in the replicates can result in a falsely high CV_A and an erroneous CV_I while failure to remove outliers from results from each of the individuals can result in a falsely increased CV_I . Finally, outliers among the mean values of the

individuals (level 3) are assessed. A simple strategy to perform this process is to use Reed’s criterion—that the difference between any mean value and the next value in the series should be less than one-third of the overall range of all values. Another useful approach for the assessment of outliers between individuals is a simple graphical approach in which the mean values and the range of all these values are plotted for each individual (on the y-axis) against concentration or activity (on the x-axis). An example is provided in Fig. 4.1 and discussed later in this chapter. Failure to exclude outliers of the mean values of the different individuals will result in a falsely large CV_G , and because the overall mean value will be different; this may also affect CV_A and CV_I depending on the transformation chosen.

Normal distribution. If the data are not normally distributed, CIs cannot be calculated using formula-based methods. It is important to specify that the normality relates to the model effects; that is, that both the analytical variation around the true sample value and the individuals’ variation around their homeostatic set point are normally distributed. It does not relate to the total pooled data. Pooling the standardized residuals for each level, namely, residuals from replicates (difference between replicates and mean of replicates from each sample), residuals from samples (difference between mean of samples and mean for the individual), and residuals from subjects (differences between individual means and total mean), can be used to assess normality.

Example: Assume observations of 2.25, 2.50, and 2.75 are from individual A and 3.50, 4.00, and 4.50 from individual B. Standardized residuals are generated by first dividing by the mean for each individual. Individual A has average 2.50, so standardized observations are 0.90, 1.00, and 1.10, and corresponding standardized residuals are -0.10 , 0.00 ,

and 0.10. Individual B has average 4.00, standardized observations 0.875, 1.00, and 1.125, and corresponding residuals -0.125 , 0.00 , and 0.125 . The pooled standardized residuals are $(-0.10, 0.00, 0.10, -0.125, 0.00, 0.125)$. The standardized residuals can then be examined using Kolmogorov-Smirnov or Anderson-Darling or other techniques for the assessment of normality.

Homogeneity. Applications of within-subject biological variation data, particularly for estimation of RCVs, depend on the within-subject variation data being homogeneously distributed. If the specimens have not been obtained from a homogeneous population, the results will not be representative of the population, only an average individual, and stratified analysis by subgroups should be applied. Thus, although estimates of CV_I and RCVs can be calculated, these are not generalizable to the overall population. It is therefore important to know that the variances in specimens drawn from a population are “homogeneous” by definition, and consequently, that the ranked cumulative distributions of these variances are distributed around the true variance of the population according to χ^2/df (χ^2 distribution for degrees of freedom [df] according to the individual sample sizes). In contrast, when a series of different variances have a dispersion around the pooled variance according to a χ^2/df distribution, they are considered to be heterogeneous. This can be illustrated by plotting the cumulated ranked fractions of within-subject variations as a function of the within-subject variation estimates on a Rankit scale (Fig. 4.2). If homogeneous, this curve will fit to the theoretical of the square root of the pooled variance multiplied by χ^2/df . Variance homogeneity can also be tested further by Bartlett’s test. Although Cochran’s test of the variances of the mean values of the specimens is primarily an outlier test, it also can be used as a test for homogeneity.

After testing for homogeneity, it is important to indicate how many individuals and results had to be removed to obtain homogeneity of the data used to estimate the CV_I . This again provides an indication of the representative nature of the data and underscores its suitability for wide application. It is also recommended to check if excluded individuals share common traits that can explain their heterogeneity, which can be valuable information to the applicability of the estimated CV_I .

Data Analysis

There are several estimators available: ANOVA, maximum likelihood (ML), restricted maximum likelihood (REML), minimum variance quadratic unbiased estimator (MIVQUE), and weighted analysis of means (WAM). For balanced designs, the choice of estimator is not important; however, for unbalanced designs, the REML, MIVQUE, or WAM are preferred for the variance components. These estimators are available in most statistical software packages using general linear models or generalized linear models.

In previous publications, many have not used formal ANOVA but instead have simply used subtracted

variances. The thesis is that, because preanalytical sources of variation have been minimized and can be considered negligible, the total CV (CV_T) of a set of results from each cohort of individuals includes CV_A , CV_I , and CV_G . Then, because:

$$CV_T = [(CV_A)^2 + (CV_I)^2 + (CV_G)^2]^{1/2}$$

the components can be calculated by simple subtraction. However, this approach will require calculations including degrees of freedom and, therefore, a formal ANOVA is a simpler approach for correct calculations and can take into account unbalanced designs. Additionally, in many of these studies, CV_A has been estimated based on quality control materials, the outliers have not been assessed, and a normal distribution and homogeneity of data are assumed; in consequence, estimates of the components of biological variation are likely to be less precise.

Fig. 4.2 Variance homogeneity plots. Rankit plots show the accumulated fractions as function of within-subject biological coefficient of variations (CVs). The filled circles represent individual CVs for healthy individuals; the line indicates the expected distribution of measured CV for “true” CV values of 17.3% for porphobilinogen (PBG) (A) and 38.1% for porphyrins (B). The Cochran test gives values of 0.11 for PBG and 0.25 for porphyrins, and a value indicating heterogeneity is >0.17 . CVs, Coefficients of variation. (From Aarsand, A. K., Petersen, P. H., & Sandberg, S. [2006]. Estimation and application of biological variation of urinary delta-aminolevulinic acid and porphobilinogen in healthy individuals and in patients with acute intermittent porphyria. *Clinical Chemistry*, 52, 650–656.)

DATABASES

Many data have been generated over the last 45 years on the components of biological variation in a broad range of measurands. Before considering the uses of the existing published data, it is necessary to consider their reliability. In many publications, duplicate measurements are lacking and outlier analysis and homogeneity testing have not been performed. For a few measurands, reviews have been performed on the robustness of estimates; examples are glycated hemoglobin (HbA_{1c}) and serum enzymes (Fig. 4.3). These reviews concluded that there is a great variation of CV_I estimates, probably due to factors including examination methodology, population selection, specimen collection frequencies, protocol application, and statistical analyses.

Current Databases and Their Merits and Disadvantages

As stated previously, derivation of the components of biological variation is not without difficulties and requires considerable resources; hence the need for a biological variation database of published information. Generation of such a comprehensive database was initiated in 1997 by the Analytical Quality Commission of the Spanish Society of Clinical Chemistry (SEQC), and it was first published in 1999. The last update of this database was in 2014. The database, which has been much cited and widely used, has many advantages. CV_I has been determined for 358 measurands in 247 articles, and this large resource has been developed and refined over nearly 20 years. Data are available on measurands in various matrices, namely, serum ($n = 185$), plasma ($n = 74$), whole blood ($n = 55$), and urine ($n = 47$).

However, due to concerns over the quality of evidence available on biological variation, the database should be used with caution. In addition, this database includes lack of data for many measurands of interest in laboratory medicine, and there has been a paucity of new publications available each

Fig. 4.3 Estimates of within-subject biological variation from different studies for three enzyme activities. ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CV, coefficient of variation. GGT, γ -glutamyl transferase. (From Carobene, A., Braga, F., Roraas, T., Sandberg, S., & Bartlett, W. A. [2013]. A systematic review of data on biological variation for alanine aminotransferase, aspartate aminotransferase and γ -glutamyl transferase. *Clinical Chemistry and Laboratory Medicine*, 51, 1997–2007.)

year for inclusion in the database, with only 25% published since 2000. Limited biological variation data are available for some measurands; for example, 202 were found in a single publication, 129 had data from 2 to 9 publications, and 27 had data from 10 or more publications. Further, CIs for the estimates, allowing for the comparison of these results, are lacking, and thus, the robustness of the data is difficult to assess.

Due to growing concerns about the apparent heterogeneity and applicability of the estimates, an Expert Working Group on Biological Variation of the European Federation of Clinical Chemistry and Laboratory Medicine (EFLM) produced a checklist to enable standardized production and reporting of biological variation data. The checklist identifies key elements that are essential for the safe, accurate, and effective transfer of biological variation data sets across health care systems. Following this work, a new EFLM Task and Finish Group has produced another tool, the Biological Variation Data Critical Appraisal Checklist (BIVAC), which is used to assess the methodological quality of existing studies. The result from this work will be used to populate a new database on the EFLM website with those estimates that have sufficient quality. An example of data generated on nine enzymes in serum using these up-to-date approaches has been recently published. Moreover, compliance with the checklist for new studies will enable authors, reviewers, and journal editors to ensure that studies are fit for purpose, appropriately powered, share common terminology, and deliver robust estimates of CV_I and CV_G, accompanied by the key metadata to enable general application.

Biological Variation in Health and Disease

Because the quality of published papers varies, it is strongly recommended that all users investigate the sources and quality of the data selected before application. It is planned that high-quality data will soon be available once the EFLM database is up and running. Some argue that many of the data on the components of biological variation are inappropriate for wider use in laboratory medicine because they have been derived from studies on healthy individuals, and not on patients with disease who are the primary targets of most laboratory examinations.

The group from the Analytical Quality Commission of the SEQC has published a database on the components of biological variation in disease. The 2014 database has information on 97 measurands in subjects with 41 disease states. This work indicates that estimates of CV_I are generally independent of the state of health, except when the measurand is the one that is pathologically changed, such as tumor markers in patients with cancers.

Generation of Data from Patient Populations

Because estimates of CV_I, a measure of the homeostatic mechanisms in individuals, seem constant, “big data” from hospital laboratories might also be used to determine this component of biological variation. For example, estimation of CV_I of HbA_{1c} was done in specimens taken routinely from children

with cystic fibrosis who had no evidence of diabetes mellitus or impaired glucose tolerance. Similarly, it would be difficult to justify collecting multiple samples from apparently healthy individuals for examinations, such as arterial pH, gas partial pressures, and electrolytes; derivation of CV_I from results of examinations in diseased individuals performed regularly in the intensive care unit has provided reliable estimates. These interesting examples showed that, although it is preferable to undertake the well-documented experimental protocols and statistical analyses, novel approaches might be required for examinations where the generation and application of traditional estimates of CV_I are difficult.

INTERPRETATION AND USE OF DATA

Individuality

The results of most examinations in laboratory medicine are compared with conventional population-based reference intervals or sometimes fixed limits for clinical decision-making. Reference intervals represent the values found in 95% of the reference population. The ramification of biological variation on the use of reference intervals is determined by the individuality of the measurand.

Fig. 4.1 shows a graph, which should always be prepared when generating data on the components of biological variation to visually assess the presence of outlying observations. This shows the means and extreme values in a cohort of 27 older adults for serum creatinine concentration. Subjects 1 to 13 were women and subjects 14 to 27 were men. The conventional reference intervals for creatinine generated in the laboratory for individuals older than 55 years of age were 60 to 98 $\mu\text{mol/L}$ (0.68 to 1.10 mg/dL) for women and 66 to 128 $\mu\text{mol/L}$ (0.75 to 1.45 mg/dL) for men.^a The following conclusions can be drawn when assessing the data in Fig. 4.1:

- No individual has observed values that span the entire reference interval.
- Most individuals have all observed values within the reference interval.
- The means of the observed values of most individuals lie within the reference interval, but they are different from each other.
- A few individuals have observed values that span the lower or the upper reference limit, and these individuals have values that change from usual to unusual over time.

It is clear that CV_I (the variation around the homeostatic set points) of creatinine is smaller than the CV_G (the difference among homeostatic set points). In numerical terms, CV_I is 4.3% and CV_G is 18.3%. Thus CV_I is less than CV_G , meaning that the measurand has marked individuality. This characteristic can be expressed mathematically as an **index of individuality** (II) and is best calculated as: $II = (CV_A^2 + CV_I^2)^{1/2} / CV_G$. It is common now for II to be simply calculated as CV_I / CV_G . This is satisfactory if CV_A is less than $\frac{1}{2} CV_I$, as is often the case with modern analytical technology and methodology,

because CV_A will then contribute little to the numerator $(CV_A^2 + CV_I^2)^{1/2}$. Most common measurands have marked individuality with a low II.

This example provides a biological explanation for the fact that serum creatinine concentration, when compared with conventional reference intervals, even if partitioned by age or sex, does not have high sensitivity for the detection of mild renal impairment, and provides a sound rationale for the undoubted benefits of the estimated glomerular filtration rate. The estimated glomerular filtration rate uses formulae that take age, sex, and ethnicity into account, as well as the serum creatinine concentration. This example also highlights that most measurands examined in laboratory medicine are not very useful in population screening or in case finding.

Consequences for Population-Based Reference Intervals

The consequences of individuality were first postulated by Harris who showed that, when II is high (the criterion usually applied is $II > 1.4$), the distribution of values from any single individual will cover much of the entire dispersion of the reference interval derived from values found in reference individuals. In contrast, if II is low (especially when $II < 0.6$), the dispersion of values for any individual will span only a small part of the conventional population-based reference interval.

The ramifications of this individuality on the interpretation of the results of examinations are profound. When II is low, most individuals can have values that are unusual for them, but these will often lie within the reference interval. Consequently, these results would not be flagged by laboratories as deserving further attention because, although they are unusual for that individual, they are within the reference interval. Moreover, the users of the laboratory results would be highly unlikely to pay attention to such unusual values. Thus taking one specimen from an individual and comparing, for example, its creatinine result to the population-based reference interval will not be an effective way of picking up the small changes often seen in early pathological processes. However, when only one sample is examined in an individual, the II will have no influence on the percentage of false positives and true positives detected, irrespective of whether the upper reference limit or a clinical decision limit is used. However, if a “confirmatory” measurement is performed, the II is important. For quantities with a very low II, such as creatinine, the new result will be close to the first, and will only provide limited new information. For quantities with a high II, a repeat measurement will decrease the number of true positives and false positives.

If II is defined as CV_I / CV_G , this ratio must be made larger to make conventional population-based reference intervals of higher clinical usefulness, especially in diagnosis, case finding, and screening, when no previous results on an individual are available. This is sometimes easily achieved because CV_G can be made smaller by stratifying (or partitioning) the data. An example is shown in Table 4.2.

^aLaboratories should verify that these ranges are appropriate for use in their own settings.

TABLE 4.2 Within-Subject (CV_I) and Between-Subject (CV_G) Biological Variation of Urine Creatinine and Indices of Individuality (II)

Group	CV _I (%)	CV _G (%)	II
Men (n = 7)	11.0	6.0	1.83
Women (n = 8)	15.7	11.0	1.42
Total	13.0	28.2	0.46

Table 4.2 shows that the II for the total cohort is 0.46; therefore the reference interval is of low usefulness, especially for monitoring individuals. However, for men and women taken separately, the II are 1.83 and 1.42, respectively, and reference intervals will be very useful. Stratification by sex has vastly increased the usefulness of the conventional population-based reference interval. Knowledge of individuality gives a sound scientific basis for stratification; II must be high for conventional, population-based reference intervals to be useful. Because CV_I is generally considered constant and rarely stratified, it must be CV_G that is made smaller, if possible.

REFERENCE CHANGE VALUES

Most laboratory results are used for monitoring acute diseases in the short term in secondary or tertiary care institutions or chronic conditions in primary care. *Monitoring*, by definition, means assessment of results over time. Because most measurands have marked individuality and low II, conventional population-based reference intervals provide limited assistance when serial results of an individual need to be interpreted.

Harris first introduced the concept of evaluating consecutive measurements in 1975 and 1976, and the concept was later simplified and introduced by Harris and Yasaka as the RCV, sometimes also referred to as *critical difference*. The former term is preferred to indicate an analogy with population-based reference intervals.

The result of one examination will have: dispersion = $Z \times (SD_A^2 + SD_I^2)^{1/2}$, where Z is the Z -score equal to the number of standard deviations appropriate for the probability desired. The result of a second examination will have the same dispersion, so the total dispersion of two results will be $2^{1/2} \times Z \times (SD_A^2 + SD_I^2)^{1/2}$. Thus, for two results on the same individual to be different, this inherent difference due to SD_A and SD_I must be exceeded, and this is the RCV.

The original RCV, as shown previously, is only applicable when SDs are used (i.e., changes expressed in units). When used for changes expressed in percentages (i.e., CV_A and CV_I combined using CVs), a transformation is required. This is due to the fact that the sum of normally distributed variables is normally distributed, but the ratio between normally distributed variables is not.

A sufficient approximation for RCV based on an already established CV_I and the individual laboratory's CV_A can be estimated using the formula:

$$SD_A^2 = \log_e \left(\left(\frac{CV_A \%}{100 \%} \right)^2 + 1 \right)$$

$$SD_I^2 = \log_e \left(\left(\frac{CV_I \%}{100 \%} \right)^2 + 1 \right)$$

$$RCV \% = \pm 100 \% \times \left(\exp \left(\pm Z_\alpha \times \sqrt{2} \times \sqrt{SD_A^2 + SD_I^2} \right) - 1 \right)$$

Example: With a within-subject biological variation found to be CV_I = 5.1% and between-run CV_A from the laboratory = 1.4%, the log_e-transformed measure of variability is $SD_I^2 = \log_e(0.051_A^2 + 1) = 0.00259762$ and $SD_A^2 = \log_e(0.014_A^2 + 1) = 0.00019598$. The correct RCV in % can then be calculated as $RCV = \pm 100 \times \left(\exp \left(\pm 1.65 \times \sqrt{2} \times \sqrt{0.00019598 + 0.00259762} \right) - 1 \right) = (-11.6\% + 13.1\%)$. The RCVs are skewed, with bigger tolerance for a rise than a fall in values.

It is usually assumed that preanalytical sources of variation are negligible, and in clinical and laboratory practice this means having well-documented standard operating procedures for patient preparation and specimen collection, transport, and handling before analysis, as well as appropriate training of staff performing these tasks. Moreover, it is important to realize that changes in the bias of the analysis between the collections of the serial specimens can also add to the RCV; if these can be quantitated, as a difference due to bias in percentage terms, ΔB , the formula becomes $RCV = \Delta B + 2^{1/2} \times Z \times (SD_A^2 + SD_I^2)^{1/2}$. However, in a single laboratory the main source of ΔB over time is due to recalibration, and this “random” bias is usually an integral component of the longer term CV_A as estimated from replicate analyses of internal quality control materials. Thus it can be assumed that a “systematic” bias of the analysis does not change during the period between the two analyses, and the simpler RCV formula applies.

It is often assumed that a Z -score of 1.96 for $P < .05$ (and sometimes also 2.58 for $P < .01$) is appropriate. It is almost ubiquitously stated in studies on biological variation that the RCV is calculated as $2.77 \times (SD_A^2 + SD_I^2)^{1/2}$. This is incorrect for various reasons. These Z -scores are termed bidirectional (or two-tailed or two-sided), and this infers that the difference between the two serial results can be either an increase or a decrease. However, in most situations, clinical decisions rely on the assessment of a significant decrease (e.g., of HbA_{1c} after treatment for diabetes mellitus or in glucose after adjustment of insulin dosage) or a significant increase in the measurand (e.g., an increase in serum creatinine to assess acute kidney injury, or serum troponin after acute chest pain). Thus unidirectional (one-tailed or one-sided) Z -scores must be used in most clinical situations to facilitate correct interpretation; these are 1.65 for $P < .05$ and

2.33 for $P < .01$. Precise definition of the real clinical setting and accurate description of what is considered a “change” in terms of “increase” or “decrease” and their many synonyms are required for correct calculation and use of RCVs in clinical decision making.

It is also important to recognize that clinical decision making is not always done at $P < .05$, which is the most commonly used probability in analysis of research data. The semantics used are crucial to understanding the probability that is clinically appropriate. An example was given in a recent study on RCVs for dehydration markers, which, in addition to graphs that showed probability against change for plasma osmolality, urine specific gravity, and body mass, integrated a series of semantic interpretative anchors; namely, change was “likely” at $P > .80$, “more likely” at $P > .90$, “very likely” at $P > .95$, and “virtually certain” at $P > .99$. RCVs should be used in a spectrum of postanalytical processes, including provision of graphs and tables of change versus probability, Δ -checking, and flagging of significant changes at different levels of probability on laboratory reports.

In addition, because RCV is dependent on both SD_A and SD_I , RCVs must be calculated for each individual laboratory since they depend on the SD_A achieved locally. Furthermore, it is essential that the SD_I used is reliable and obtained from a population with a homogeneous SD_I that is similar to the population for whom the RCV is being applied. In addition, the time interval used for obtaining the SD_I must be comparable to the one used in practice. Thus laboratories can calculate relevant RCVs by using SD_A derived from their own internal quality control programs, using data close to clinical decision-making concentrations or activities, along with robust SD_I estimates from publications cited in the most up-to-date database.

Traditional RCVs are believed by some to be rather simplistic, especially because they only address how likely it is that a certain change can be explained by SD_A and SD_I , but not the probability that a change in the disease state has occurred. It has been suggested that a tool for better understanding and interpretation of measured differences in monitoring is needed; that the concepts of sensitivity, specificity, likelihood ratios, and odds used for diagnostic test accuracy evaluations should be applied to monitoring by substituting measured concentrations with measured differences. It was suggested that this idea expanded the earlier concept of RCV by making it possible to have an estimate of the posttest odds for a certain difference to occur. Consequently, the likelihood ratio for change increases with a larger measured difference, and when used together with the pretest odds or pretest probability, the posttest odds and posttest probability, which are related to the clinical situation, can be calculated (see [Chapter 2](#) for details).

It has been proposed that the probability of significance of any difference seen in clinical practice between two results can be calculated using a simple rearrangement of the RCV equation making the Z -score (and thus the probability) the unknown, namely:

$$Z = \text{difference} / \left[2^{1/2} \times (SD_A^2 + SD_I^2)^{1/2} \right]$$

This does not seem to have been applied much in practice, but there is clearly scope for adoption of this technique to enhance interpretation of serial results. Exactly as for RCVs, this application would have important consequences for SD_A ; the smaller the SD_A , the smaller the RCV will be for any probability, and the significance of any difference seen will be of higher probability.

Reference Change Values for More Than Two Serial Analyses

Frequently, in practice, more than two results of analysis are available for the individuals over time. Using the traditional RCVs described previously, it is only possible to calculate the significance of changes between each of the two consecutive analyses. Thus an RCV method including all available serial results might be useful for interpretation of significant differences over time.

Mathematical methods have been developed to assess serial results from an individual, which are sometimes called methods for time series analysis. One is called the *homeostatic model*. This model assumes that the measurand varies randomly around a homeostatic set point. After collection of results from a small number of analyses, the mean and SD are calculated. The next result should fall within the range calculated from the mean and the SD. Then, new data from the same individual are used in an ongoing manner to refine the estimates of the mean and SD for that individual to interpret whether the next new result has changed significantly from previous data. In contrast, the “random walk” model assumes that the measurand behaves randomly, and there is no homeostatic set point. The dispersion of each result is calculated. However, instead of calculating a mean for the individual and recalculating this mean as further data are gathered, it is assumed that the most recent result is the starting point from which to assess whether change has occurred. These models have not been widely applied; they generate many false positive signals that change has occurred, when there is no obvious usual or pathological change. They also seem too complex and time consuming to be used in everyday practice.

Recently, studies on both unidirectional and bidirectional changes in serial results that used computer simulations have been performed. Factors used to multiply the first result from an individual were calculated to create the limits for constant cumulated significant differences. The factors were shown to become a simple function of the number of results and the total CV. The first result is multiplied by the appropriate factor for an increase or a decrease, which gives the limits for a significant difference. It remains to be seen if such apparently simple techniques become used in practice.

Analytical Performance Specifications

Analytical performance specifications (APSs) are the numerical standards of analytical performance that are required to facilitate optimum patient care. There are many strategies available to set these specifications, which have been described over time as this facet of laboratory medicine has evolved. A concise historical perspective has been published recently.

Following pioneering studies done in the United States on the definition of the components of biological variation, a College of American Pathologists conference held in 1976 supported the concept that APS should be best based on biology. The consensus statement, restated in current terms and symbols, was: “For group screening, in which an individual is to be selected from a population, a specification for imprecision (CV_A) is defined as: $CV_A = 0.5 \times (CV_I^2 + CV_G^2)^{1/2}$,” and “For individual single and multipoint testing, in which an individual is evaluated on the basis of discrimination values: $CV_A = 0.5 \times CV_I$.”

As the topic of APS matured and a profusion of recommendations appeared, many leading professionals in laboratory medicine realized that there was a need for a global consensus on the setting of such specifications. The Stockholm Conference held in 1999 on “Strategies to set global analytical quality specifications in laboratory medicine” achieved this and advocated the ubiquitous application of a hierarchical structure of approaches, based on a model proposed by Fraser and Petersen. The hierarchy had five levels, stated as: (1) evaluation of the effect of analytical performance on clinical outcomes in specific clinical settings; (2) evaluation of the effect of analytical performance on clinical decisions in general, using (a) data based on components of biological variation or (b) analysis of clinicians’ opinions; (3) published professional recommendations from (a) national and international expert bodies or (b) expert local groups or individuals; (4) performance goals set by (a) regulatory bodies or (b) organizers of external quality assessment (EQA) schemes; and (5) goals based on the current state of the art as (a) demonstrated by data from EQA or proficiency testing scheme, or (b) found in current publications on methodology. Since the Stockholm conference, there have been further proposals for setting APS, but all of these have included biological variation data in their derivation.

In 2015 the EFLM organized the First Strategic Conference on Defining Analytical Goals 15 Years after the Stockholm conference. The consensus statement and formal papers emanating from the speakers are included in a Special Issue of *Clinical Chemistry and Laboratory Medicine*, and they represent an invaluable up-to-date resource on all aspects of setting APS and on generation and application of data on biological variation. The consensus was that the Stockholm hierarchical approach was supported but could be simplified. In this revision, the hierarchy was streamlined and represented by three different models to set APS.

Model 1 is based on the effect of analytical performance on clinical outcomes using direct (1a) or indirect (1b) outcome studies. The latter investigates the impact of analytical performance of the investigation on clinical classifications or decisions and thereby on the probability of patient outcomes.

Model 2 is based on components of biological variation of the measurand.

Model 3 is based on the analytical state of the art.

The three models use different principles, and some models will be better suited for certain measurands than

for others. Application of model 1 is difficult and will probably be limited to a few measurands. An EFLM Task and Finish Group established after the conference has proposed and visualized through a flow chart a model for how to allocate different measurands to different models. In general, it states that model 2 can be used when the measurand has a stable concentration or activity in serum/plasma and the measurand is not suited for clinical outcome studies or such data do not exist. Generally applicable APS will still be best based on biological variation data for most measurands. In view of the caveats regarding the reliability of certain data on the components of biological variation and the central role measures of biological variation play, there will be significant advances when the EFLM Task and Finish Group on the Biological Variation Database fulfills its remit of creating a database with high-quality estimates, and its recommendations on standards of generation and reporting of data are carried through into practice.

Specifications for Analytical Imprecision

This approach became more popular as the quantity of data on the components of biological variation increased. In most cases, the APS for CV_A was simply taken as $CV_A = 0.5 CV_I$, with the rationale that the same technology and methodology were used to examine specimens in both of the clinical settings of group screening and individual single and multipoint testing (and other situations). In consequence, the APS derived for the most stringent situation would allow both specifications to be met for all purposes.

Specifications for Analytical Bias

Examination bias was not considered in most early works on setting APS, possibly because the thesis was that laboratories all had their own reference intervals to which the results of their analyses were compared. However, as the interest in harmonization of laboratory data across time and geography increased, and the benefits for harmonized reference intervals were appreciated, criteria for bias needed to be developed. Therefore it was proposed that the APS for bias (B), to allow use of harmonized reference intervals, should be $B < 0.25(CV_I^2 + CV_G^2)^{1/2}$.

Specifications for Allowable Total Error

As the concepts of total laboratory quality management evolved, and the idea that random and systematic sources of variation (imprecision and bias) were both important, it became clear that total analytical error was the most relevant clinically. It was proposed that the linear model of combining imprecision and bias could be used to set APS for what was termed total error allowable (TEa) as a simple linear addition; for $P < .05$: $TEa < 1.65 \times 0.5 CV_A + 0.25(CV_I^2 + CV_G^2)^{1/2}$. It should be noted that this model for combining imprecision and bias is only one of the many models available. An EFLM Task and Finish Group has summarized the pros and cons of the concepts of allowable total error and measurement uncertainty.

The total error concept is widely used in current practice in laboratory medicine, albeit sometimes with a different multiplier for the imprecision term, to deliver different levels of probability. Application of this has become very widespread because the formula is simple, many data on biological variation exist, and they are directly related to the general use of results of examinations in laboratory medicine. However, concerns have been expressed. First, because the biological variation data currently used for some measurands vary, and second, because the APS derived using biological variation are unattainable for some measurands with current technology and methodology, including serum sodium, chloride, and calcium. However, some APS were easy to obtain for others, including serum urea, triglycerides, and many enzyme activities. A three-tier model to cater for this was proposed, giving minimum, desirable, and maximum APS based on biological variation using $0.25 CV_A$, $0.50 CV_A$, and $0.75 CV_A$ for imprecision and $0.125 \times (CV_I^2 + CV_G^2)^{1/2}$, $0.25 \times (CV_I^2 + CV_G^2)^{1/2}$, and $0.325 \times (CV_I^2 + CV_G^2)^{1/2}$ for bias, respectively. Furthermore, because analytical technology has evolved rapidly over recent time, and examination performance has improved, it has been suggested that a fourth “ideal” level should be introduced with multipliers of 0.1 for both imprecision and bias. Combinations of the three (or four) levels can be done to obtain relevant performance specifications for TEa.

Specifications Derived from Opinions of Clinicians

Because it is the users of the results of laboratory tests that apply the data provided, it is logical to think that they should set analytical quality requirements that facilitate their decision making. One way of attempting to do this is with clinical vignettes in which the clinician provides information about the change in serial results, which is required to stimulate a clinical decision. The principle behind the studies should be that a difference in serial results is due to preanalytical sources of variation (CV_P), CV_A , CV_I , and changes in bias (ΔB), using the transformation mentioned above from CV to SD:

$$\text{difference} = 2^{1/2} \times Z \times [SD_P^2 + SD_I^2 + SD_A^2]^{1/2} + \Delta B$$

now, let SD_P and ΔB be zero and rearrange the equation:

$$SD_A = [\text{difference} / (2^{1/2} \times Z + SD_I^2)]^{1/2}$$

Studies have been done using this model on a variety of measurands, and have included some studies that involved patients undertaking self-testing. An early example is provided by the studies on blood hemoglobin; other studies performed since then have investigated HbA_{1c}, glucose, prothrombin time, erythrocyte sedimentation rate, and urinary albumin. It was found that the derived APS depends on the clinical setting and local management pathway, the semantics of the questions posed, how close the result was to a decision limit or reference limit, and probably on perceptions related to current analytical performance. Not

unexpectedly, there was large between-clinician variation in response. This approach is probably possible only for the assessment of a single measurand in a well-specified clinical situation. In addition, it has been suggested that this strategy is possible only for measurands that have a major role in monitoring and/or diagnosis and where more or less uniform recommendations guide clinical standards of practice.

Specifications for Measurement Uncertainty

Because there is now a requirement for medical laboratories to document the measurement uncertainty to comply with ISO 15189, there should be consideration of the setting of APS for this characteristic. Because the fundamental principles are that bias should be eliminated (if possible) and all sources of variation should be added linearly as variances, then the only possible performance specifications for measurement uncertainty are that $CV_A < f \times CV_I$, where $f = 0.10, 0.25, 0.50, 0.75$ for ideal, optimum, desirable, and minimum levels of performance, respectively, but, again, this is dependent on reliable data being available for CV_I .

Specifications for Other Applications

Data on biological variation have been used to generate performance specifications in other than general clinical settings, including an evaluation of systems, reference methods, and for the allowable difference in bias % ($\Delta B\%$) between two measurement systems or devices used to generate results on the same individuals, which is $\Delta B\% < 1/3 CV_I$.

OTHER APPLICATIONS

Calculation of Reliability Coefficient

The individuality of tests and the consequences of the marked individuality (low II) of most measurands in laboratory diagnosis, case finding, screening, and monitoring have been discussed. Epidemiologists and others use similar information to the II, but in a slightly different way. The reliability coefficient is used, which is calculated as $CV_G^2 / (CV_A^2 + CV_I^2 + CV_G^2)^{1/2}$, which is the between-subject variance divided by the total variance. The reliability coefficient, usually called R , is numerically equal to the correlation coefficient of repeated measurements. It can be between 0 and 1. If R approached 0, II would be high, and if R approached 1, then II would be low. Most measurands have high values for R .

Number of Samples Needed

In usual clinical practice, only one sample is taken. Analytical result variation can be reduced by multiple sampling (or multiple analyses), and the variation is made smaller by the square root of the number of replicates. To estimate the number of specimens needed to determine the homeostatic set point within a certain percentage error with a stated probability, a

simple rearrangement of the usual standard error of the mean formula is used, namely:

$$n = \left(\frac{Z \times \sqrt{CV_A^2 + CV_I^2}}{D} \right)^2$$

where Z is the Z -score appropriate for the probability, and D is the desired percentage closeness to the homeostatic set point. It is important to note that taking multiple specimens and undertaking replicate analyses does affect the overall variability of the individual analytical result; the dispersion (expressed as 1 CV) can be calculated as:

$$\text{dispersion} = Z \times \left[\left(CV_A^2/nA \right) + \left(CV_I^2/nS \right) \right]^{1/2}$$

where Z is the number of standard deviations appropriate to the probability selected, nA is the number of replicate examinations, and nS is the number of specimens. The relative magnitudes of CV_A and CV_I are important in deciding if a lower dispersion is required, whether it is better to undertake replicate analyses on one specimen or singleton analysis on multiple specimens. Calculators for this can be found, along with a more detailed discussion of this topic, with real examples, at <https://www.westgard.com/>.

Reporting Results, Selecting the Best Specimen to Collect, and Choosing the Best Investigation

It is sometimes possible to report the results of investigations in different ways. For example, measurands in urine, such as creatinine, can be reported as concentration or output per day, and many others (e.g., electrolytes or proteins) are reported as a creatinine concentration ratio. Moreover, for some measurands, it is possible to collect different samples for the same clinical purpose (e.g., early morning or random or timed urine specimens for assessment of low concentration albumin and protein). In certain clinical situations, alternative investigations that might be considered to have a somewhat similar purpose are available, such as serum creatinine and cystatin-C, or blood HbA_{1c} and serum fructosamine. Knowledge of the components of biological variation can assist in making decisions about reporting results, selecting the best specimen to collect, and choosing the best test.

To undertake such comparisons, the influences of biological variation should be considered. The ideal measurand would have low CV_I so that a single analysis will give a good measure of the true value for that individual. Moreover, this would allow easy monitoring over time and detection of significant differences, because the RCV would be low, provided that the CV_A was also low. In addition, the ideal measurand would have no heterogeneity of CV_I among individuals and across studies, and would not be dependent on age and sex and other possible confounding factors so that the simple general formulae given in this chapter would hold for all.

Method Development and Evaluation

Introduction of new investigations is an ongoing task for most medical laboratories. Some years ago, Zweig and Robertson

suggested that the introduction of a new procedure should be similar to the structured evolution of a new drug through phased trials. They suggested that the phases should be the following: analytical investigation and assessment of reliability and practicability characteristics; overlap investigation involving the generation of reference intervals and the assessment of values in disease; clinical investigation and evaluation of sensitivity, specificity, and predictive value; outcome investigation of whether individuals gain an advantage; and, finally, investigation of usefulness, which is a cost-benefit analysis with respect to individuals and the population. In contrast to the linear models, another approach has been proposed in which the essential components of analytical and clinical performance, clinical and cost effectiveness, and the broader impact of testing are assembled in a dynamic cycle. This approach emphasizes the interaction of the different components, and that clinical effectiveness data should be fed back to refine analytical and clinical performances to achieve improved outcomes.

One aspect that is not covered in any of these strategies, however, is the need to generate and apply data on biological variation early in the evolution of any investigation. Data on biological variation allow the setting of APS, calculation of the significance of changes in an individual, and assessment of the use of the generated population-based reference intervals. Generation and application of data on biological variation are essential prerequisites for introducing new laboratory investigations. Moreover, the data are also necessary for objective analysis of the often somewhat subjective guidelines from professional bodies that give recommendations on interpretation of numerical results and on APS; unfortunately, these recommendations are often flawed.

OVERALL CONCLUSIONS

Numerical estimates of within-subject and between-subject biological variation are best generated by analysis of a series of specimens taken from a cohort of individuals, analyzed in duplicate, and followed by statistical analysis of the sources of variation. The proper design and performance of such studies is complex. However, biological variation data have numerous applications, including:

- The determination of the individuality of a measurand and the usefulness of conventional population-based reference intervals
- The statistical significance of changes in serial results from an individual
- APS for imprecision, bias, allowable total error, measurement uncertainty, and other characteristics

Currently, there are concerns regarding the robustness of certain of the published data on biological variation, but important initiatives are on their way to provide easily accessible robust and globally adoptable estimates. Recent recommendations should be followed in the generation, reporting, and application of biological variation data.

POINTS TO REMEMBER

Biological variation may be cyclical and daily, monthly, or seasonal, but most measurands have random variation around homeostatic set points.

The generation of high-quality data on within-subject and between-subject components of biological variation requires adherence to strict experimental and statistical protocols.

Biological variation estimates are available for many measurands, but their reliability should be questioned, and users should ensure the relevance of published data to their applications.

Data on biological variation are used, inter alia, to determine:

- The individuality of a measurand and the usefulness of conventional population-based reference intervals
- The statistical significance of changes in serial results in an individual and the probability that any change documented is significant
- APS for imprecision, bias, TEa, measurement uncertainty, and other characteristics

REVIEW QUESTIONS

1. Which of the following usually best describes the variation in the concentration or activity of most measurands in laboratory medicine?
 - a. Circadian rhythms
 - b. Monthly cycles
 - c. Systematic trends
 - d. Random variations
 - e. Seasonal fluctuations
2. Which of the following strategies is recommended to best set general analytical performance specifications?
 - a. Effect of analytical performance on clinical outcomes
 - b. Fractions of biological variation component estimates
 - c. Professional body recommendations
 - d. The limits of acceptance used in external quality assessment or proficiency testing
 - e. The state of the art
3. Which of the following is irrelevant to the creation of Reference Change Values?
 - a. Within-subject biological variation
 - b. Analytical bias
 - c. Analytical imprecision
 - d. Preanalytical sources of variation
 - e. Between-subject biological variation
4. What analytical imprecision should be used when the reference change value is to be created for a measurand that will be used by your own laboratory?
 - a. The analytical imprecision obtained from duplicate analyses obtained during the study of the biological variation
 - b. The best analytical imprecision you can obtain in your laboratory
 - c. The analytical imprecision obtained in your laboratory during same time period as the time interval between the samples examined
 - d. The analytical imprecision as assessed from an external quality assessment scheme
 - e. The analytical imprecision documented in the manufacturer's literature
5. Which of the following represents the individuality of most measurands in laboratory medicine?
 - a. The index of individuality is high
 - b. The index of individuality is low
 - c. The measurand has low individuality
 - d. The within-subject variation is larger than the between-subject variation
 - e. The analytical imprecision is lower than the within-subject variation

Establishment and Use of Reference Values

Gary L. Horowitz, Graham R.D. Jones*

OBJECTIVES

1. Define the following:
 - Clinical sensitivity
 - Clinical specificity
 - Exclusion criteria
 - Interpercentile interval
 - Outlier
 - Partitioning; partitioning criteria
 - Population-based reference value
 - Predictive value
 - Prevalence
 - Random sample
 - Range
 - Reference individual
 - Reference interval
 - Reference limits
 - Reference population
 - Reference value
 - Selection criteria
 - Subject-based reference value
 - Transferability or transference
2. List three conditions that are essential when a valid comparison of individual laboratory results with reference values is performed; state the need for establishing reference intervals.
3. Give three examples of exclusion criteria used in the production of health-associated reference values; give three examples of partitioning criteria used to subgroup a reference group.
4. State why standardization of specimen collection is important when reference values are established.
5. Compare the terms *reference value* and *reference interval*; list three categories of reference intervals.
6. Briefly state the parametric and nonparametric statistical methods of determining an interpercentile interval; state the important assumption that must be made when parametric statistics are used.
7. State the limitation of using population-based reference intervals instead of subject-based reference intervals, and state a solution to this limitation.
8. Discuss the issue of transferability of reference values with regard to prerequisites and solutions to the issue.
9. State the formulas used in calculating clinical sensitivity, clinical specificity, and predictive value of a laboratory test; given appropriate values, calculate clinical sensitivity, clinical specificity, and predictive value for a laboratory test.
10. State how the predictive value of a laboratory test is affected by prevalence.

KEY WORDS AND DEFINITIONS

Clinical sensitivity The proportion of subjects with disease who have positive test results.

Clinical specificity The proportion of subjects without disease who have negative test results.

Nonparametric analysis A statistical approach to reference value analysis that requires no assumptions about the nature of the distribution; thus it can be applied to distributions that are Gaussian or non-Gaussian.

Parametric analysis A statistical approach to reference value analysis that requires specific distributional assumptions. For example, it usually requires that the distribution of

values be Gaussian (or that the values be mathematically manipulated so that they become Gaussian).

Partitioning The use of specific criteria in the subclassification of reference groups to reduce the biologic variation in each group; the most commonly used criteria are age and sex.

Predictive value The predictive value of a positive laboratory test is the number of true-positive results divided by the total number of positive results (true-positives plus false-positives); the negative predictive value is the number of true-negative results divided by the total number of negative results (true-negatives plus false-negatives).

*The authors gratefully acknowledge the original contribution by Helge Eric Solberg on which major portions of this chapter are based.

Prevalence The proportion of subjects in a specified population who have a specified disease or condition.

Reference individual An individual selected as the basis for comparison with individuals under clinical investigation through the use of defined criteria.

Reference interval (population based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the reference population; this is frequently the central 95% of values from the reference population.

Reference interval (subject based) A set of values usually defined by an upper reference limit and a lower reference limit, representing a specified proportion of the values from a reference individual; this is frequently the central 95% of values from the reference individual.

Reference population An undefined number of individuals that represent the demographic for which the reference intervals will be used. Reference individuals are chosen, preferably at random, from this larger population to

provide reference samples for the establishment of a reference interval.

Reference value A value obtained by observation or measurement of a particular type of quantity on a reference individual; results of a certain type of quantity obtained from a single individual or group of individuals corresponding to a stated description.

Selection criteria A set of criteria that define the desired characteristics of a reference individual. The specific criteria chosen will depend on the purpose of the reference interval (RI) and the specific population the RI is intended to represent.

Transferability or Transference The adoption of reference intervals by a laboratory that were previously established elsewhere. Procedures for validation of reference intervals must be completed by the adopting laboratory prior to the use of the transferred RI to ensure that they are appropriate to the laboratory's patient population and laboratory methods.

In practice, data collected during (1) medical interviews, (2) clinical examinations, and (3) supplementary investigations are interpreted by comparison with reference data. If the condition of the patient resembles that typical of a particular disease, the clinician or health care provider may base the diagnosis on the observation (positive diagnosis). This diagnosis is made more likely if observed symptoms and signs do not fit the patterns that characterize a set of alternative diseases (diagnosis by exclusion).

Interpretation of medical laboratory data is an example of decision making by comparison. We therefore need *reference values* for all tests performed in the clinical laboratory, not only from healthy individuals but also from patients with relevant diseases. Ideally, observed values should be related to several collections of reference values, such as values from (1) healthy people, (2) undifferentiated hospital population, (3) people with typical diseases, or (4) ambulatory individuals, and to previous values from the same subjects. A patient's laboratory result is simply not medically useful if appropriate data for comparison are lacking. Establishment and use of such reference values are the topics of this chapter.

ESTABLISHMENT OF REFERENCE VALUES

Certain conditions are mandatory for making the comparison of a patient's laboratory results with reference values possible and valid:

1. All groups of reference individuals should be clearly defined.
2. The patient examined should resemble sufficiently the reference individuals (in all groups selected for comparison) in all respects other than those under investigation.

3. The conditions under which the samples were obtained and processed for analysis should be known.
4. All quantities compared should be of the same type.
5. All laboratory results should be produced with the use of adequately standardized methods under sufficient analytical quality control (see Chapter 7).
6. The clinical sensitivity, clinical specificity, and prevalence in the populations tested should be known so that laboratory tests can be interpreted intelligently (see Chapter 2).

Background

The term *normal values* has been used frequently in the past. Confusion arose because the word *normal* has several very different connotations. Consequently, this term is now considered obsolete and **should not be used**. Instead, the International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) recommends use of the term *reference values* and related terms, such as *reference individual*, *reference limit*, *reference interval*, and *observed values*. **Reference values** are results of a certain type of quantity obtained from a single individual or group of individuals corresponding to a stated description, which must be spelled out and made available for use by others.

A short description of qualifiers associated with the term *reference values*, such as *health-associated reference values* (close to what was understood by the obsolete term *normal values*), is convenient. Other examples of such qualifying words are (1) *diabetic patient*, (2) *hospitalized diabetic patient*, and (3) *ambulatory diabetic patient*. These short descriptions prevent the common misunderstanding that reference values are associated only with health.

A further distinction is made between subject-based and population-based reference values. *Subject-based reference values* are previous values from the same individual, obtained when the individual was in a defined state of health.

Population-based reference values are those obtained from a group of systematically defined reference individuals and are usually the values referred to when the term *reference values* is used with no qualifying words.

Selection of Reference Individuals

A set of explicit criteria should be used to determine which individuals should be included in the group of **reference individuals**. Such criteria include (1) statements describing the source population, (2) specifications of criteria for health, and (3) the disease of interest. The selection of reference individuals is based essentially on the application of these defined criteria to the entire group of examined candidates. The required characteristics of the reference values determine which criteria should be used in the selection process. As examples, the left-hand column of Table 5.1 provides some examples of criteria that should be considered when *excluding* individuals in the production of health-associated reference values.

Ideally the group of reference individuals should be a *random sample* of all individuals in the parent population who meet the **selection criteria**. However, a strictly random sampling scheme is impossible to obtain in most situations for a variety of practical reasons. For example, it would imply the examination and application of selection criteria to the entire population (thousands or millions of individuals) and the random selection of a subset of individuals among those accepted. Therefore using the best reference sample obtained after all practical considerations have been taken into account is necessary. Data then should be used and interpreted with due caution because of the possible bias introduced by the nonrandomness of the sample selection process.

Often, separate reference values for sex, age group, and other criteria are necessary. Thus it is important to define the *partitioning* criteria for the subclassification of the set of selected reference individuals. Some examples are provided in the right-hand column of Table 5.1. It should be noted that some criteria can be used as either exclusion or partitioning criteria, depending on the nature of the study. In practice, each partition could require as many as 120 samples; therefore the number of partitions should usually be kept as small as possible to obtain sufficient sample sizes for the derivation of valid statistical estimates.

Age and sex are the most frequently used criteria for partitioning because several analytes vary significantly among different age and gender groups. Age may be categorized by equal intervals (e.g., by decades) or by intervals that are narrower in the periods of life where greater variation is observed. In addition, the use of qualitative age groups (e.g., [1] postnatal, [2] infancy, [3] childhood, [4] prepubertal, [5] pubertal, [6] adult, [7] premenopausal, [8] menopausal, and [9] geriatric) often may be appropriate. Height and weight also have been used as criteria for the categorization of children.

Specimen Collection

Preanalytical standardization of (1) preparation of individuals before sample collection, (2) the sample collection itself,

TABLE 5.1 Examples of Exclusion and Partitioning Criteria

Exclusion Criteria	Partitioning Criteria
Age	Age
Alcohol intake	Blood group
Blood donation (recent)	Circadian variation
Drug abuse	Ethnicity
Exercise intensity (recent)	Exercise intensity (recent)
Fasting vs. nonfasting	Fasting vs. nonfasting
Sex	Sex
Hospitalization (recent)	Menstrual cycle (by stage)
Hypertension	
Illness (recent)	
Lactation	
Obesity	Obesity
Occupation	Posture (when sampled)
Oral contraceptives	
Pregnancy	Pregnancy (by stage)
Prescription drugs	Prescription drugs
Recent transfusion	

and (3) handling of the sample before analysis may eliminate or minimize bias or variation from these factors. These steps may reduce biological “noise” that otherwise may conceal important biological “signals” of disease, risk, or treatment effect.

The magnitudes of preanalytical sources of variation clearly are not equal for different analytes (see Chapter 3). Therefore one may argue that one should consider only those factors that cause unwanted variation in the biological quantity for which reference value production is intended. Body posture during sample collection is, for instance, highly relevant for the establishment of reference values for nondiffusible analytes, such as albumin in serum, but is irrelevant for diffusible ones, such as serum sodium.

However, performing separate studies to allow for different preanalytical conditions for each constituent is impractical. In addition, several constituents are typically analyzed in the same clinical specimens. For these reasons, standardized procedures are recommended for sample collection, taking into account the requirements that will enable all the constituents under study to be measured accurately.

A special problem is caused by drug ingestion before sample collection. A distinction may be made between indispensable and dispensable medications. The latter category of drugs always should be avoided for at least 2 days before specimen collection. The use of indispensable drugs, such as contraceptive pills or essential medication, may be a criterion for exclusion or partition.

Analytical Procedures and Quality Control

Essential components of the required definition of a set of reference values are specifications concerning (1) analysis method, including information on equipment, reagents, calibrators, types of raw data, and calculation method; (2) quality control (see Chapter 7); and (3) reliability criteria (see Chapter 2). Specifications should be carefully described so

that another investigator will be able to reproduce the study and evaluate comparability of the reference values with values obtained by the methods used for production of the patient's values in a routine laboratory. To ensure comparability between reference and observed values, the same analytical method should be used. Alternatively (or in addition), one can establish comparability of methods and populations by analyzing 20 samples from reference individuals and ensuring that no more than two values fall outside the proposed limits.

Statistical Treatment of Reference Values

After the analysis of the reference specimens is performed, the reference values are subjected to a statistical treatment, which includes (1) partitioning of the reference values into appropriate groups, (2) inspection of the distribution of each group, (3) identification of outliers, and (4) determination of reference limits.

Partitioning of Reference Values

The subset of reference individuals and the corresponding reference values may be partitioned according to sex, age, and other characteristics (see Table 5.1). **Partitioning** is also known as *stratification*, *categorization*, or *subgrouping*, and its results are called *partitions*, *strata*, *categories*, *classes*, or *subgroups*. Such partitioning gives rise to narrower and potentially more appropriate reference intervals. For example, creatinine reference intervals for adult males and adult females overlap but are different because of the typical differences in muscle mass; combining them into a single interval would obscure those differences. Various statistical criteria for partitioning have been suggested, and all feature the need to collect sufficient data to allow evaluation of the partitions separately and then, if appropriate, to combine them. For example, one may test for differences in means or in standard deviations (SDs) of the separate distributions. However, note that differences in means or differences in variability may be *statistically* significant and still too small *clinically* to justify replacing a single overall reference interval with several class-specific intervals. Harris and Boyd and Lahti and coworkers have developed other criteria for partitioning and statistical methods for this purpose.

In the following sections a homogeneous reference distribution is assumed to exist—either the complete sample distribution (if partitioning is unnecessary) or a subclass distribution after partitioning.

Inspection of Distribution

It is advisable to display the reference distribution graphically and subsequently to inspect it. A histogram, as shown in Fig. 5.1, is prepared manually or by a computer program. Examination of the histogram serves as a safeguard against the misapplication or misinterpretation of statistical methods, and it may provide valuable information about the data. The following characteristics should be sought in an examination of the distribution:

Fig. 5.1 Observed distribution of 124 γ -glutamyltransferase (GGT) values in serum (IU/L). This distribution is clearly not Gaussian; it appears skewed to the right. The *upper arrow* indicates the range of observed values (highest – lowest, or $74 - 6 = 68$); the *lower arrow* indicates the difference between the highest value and the next highest value ($74 - 50 = 24$). Because the quotient ($24/68 = 0.35$) exceeds 0.33, Dixon's range test indicates that the highest value is an outlier and therefore is omitted from all further analyses.

1. Highly deviating values (outliers) may represent erroneous values.
2. Bimodal or polymodal distributions have more than one peak and may indicate that the distribution is nonhomogeneous because of the mixing of two or more distributions. If nonhomogeneity is the case, the criteria used to select reference individuals should be reevaluated or partitioning of the values according to age, sex, or other relevant factors attempted.
3. The shape of the distribution may be asymmetrical (skewed) or more or less peaked than the symmetrical and bell-shaped Gaussian distribution (non-Gaussian kurtosis).
4. Visual inspection may provide initial estimates of the location of reference limits that are useful as checks on the validity of computations.

Identification and Handling of Outliers

An outlier is an erroneous value that deviates significantly from the proper reference values. Visual inspection of a histogram is a reliable method for identification of possible outliers. However, the inspector must keep in mind that values near the farthest point on the long tail of a skewed distribution may easily be misinterpreted as outliers. If the distribution is positively skewed, inspection of a histogram displaying the logarithms of the values may aid in the identification of outliers. Some outliers may be identified by statistical tests, but no single method will detect outliers in every situation that may occur. Two main problems are often encountered:

1. Many tests assume that the type of the true distribution is known before the tests are used. Some tests specifically require that the distribution be Gaussian. However, biologic distributions are very often non-Gaussian, and their types seldom are known in advance. The Dixon-Reed range test, described in IFCC's recommendation, is relatively robust and involves identification of the extreme value as an outlier if the difference between the two highest (or lowest) values in the distribution exceeds one-third of the range of all values (see Fig. 5.1).
2. Several tests for outliers assume that the data contain only a single outlier. Thus the range test may fail in the presence of several outliers.

A method published in 2005 may provide a solution to both of these problems. The algorithm involves mathematically transforming the data so as to approximate a Gaussian distribution, calculating the range of the central 50% of the resulting distribution, and then subtracting 150% of this value from the 25th percentile and adding 150% of this value to the 75th percentile. Any values beyond these limits are considered outliers.

Deviating values identified as possible outliers should not be discarded automatically. Values should be included or excluded on a rational basis. The records of the suspect values should be checked and any errors corrected. In some cases, deviating values should be rejected because noncorrectable causes have been found, such as previously unrecognized conditions that qualify individuals for exclusion from the group of reference individuals.

Determination of Reference Limits

In clinical practice an observed patient's value usually is compared with the corresponding **reference interval**, which is bounded by a pair of reference limits. This interval, which may be defined in different ways, is a useful condensation of the information carried by the total set of reference values.

The terms *reference limits* and *clinical decision limits* should not be confused. Reference limits describe the reference distribution and provide information about the observed variation of values in the selected set of reference individuals. Thus comparison of new values with these limits conveys only information about similarity to the given set of reference values. In contrast, clinical decision limits provide optimal separation among clinical categories. Such limits usually are based on analysis of reference values from several groups of individuals (e.g., healthy individuals, patients with relevant diseases) and thus are used for differential diagnosis. Alternatively, such values are established scientifically on the basis of outcome studies and guide decisions on treatment. For an example of decision limits currently in widespread use, the reader is referred to American College of Cardiology/American Heart Association guidelines for cholesterol.

As discussed earlier, the term *reference range* has been used for the term *reference interval*, but this use should be discouraged because the statistical term *range* denotes the difference (a single value!) between maximum and minimum values in a distribution.

Categories of reference intervals include (1) tolerance interval, (2) prediction interval, and (3) interpercentile interval. The choice from among these three may be important for certain systematically defined statistical problems, but, in practice, their numerical differences are negligible when based on at least 100 reference values.

The interpercentile interval is (1) simple to estimate, (2) more commonly used, and (3) recommended by the IFCC. It is defined as an interval bounded by two percentiles of the reference distribution. A percentile denotes a value that divides the reference distribution such that a specified percentage of its values has magnitudes less than or equal to the limiting value. For example, if 47 IU/L is the 97.5 percentile of serum

γ -glutamyltransferase (GGT) values, then 97.5% of the values are equal to or less than this value.

The definition of the reference interval as the central 95% interval bounded by the 2.5 and 97.5 percentiles is an arbitrary but common convention (i.e., 2.5% of the values are cut off in both tails of the reference distribution). Another size or an asymmetrical location of the reference interval may be more appropriate in particular cases.

Of importance is the degree of uncertainty associated with a given percentile as an estimate of a population value; the magnitude of this uncertainty depends on the size of the sample, which increases when the number of observations is low. If the assumption of random sampling is fulfilled, determination of the confidence interval of the percentile (i.e., the limits within which the true percentile is located with a specified degree of confidence) is possible. The 0.90 confidence interval of the 97.5 percentile (upper reference limit) for serum GGT may, for example, be 39 to 50 IU/L. The true percentile would be expected in this interval with a confidence limit of 0.90 if all serum GGT concentrations in the total **reference population** were measured. The theoretical minimum sample size required for estimation of the 2.5 and 97.5 percentiles is 40 values, but usually at least 120 reference values are required to obtain reliable estimates.

The interpercentile interval has been determined by both parametric and nonparametric statistical techniques. The **parametric** method for the determination of percentiles and their confidence intervals assumes a certain type of distribution, and it is based on estimates of population parameters, such as the mean and SD. For example, a parametric method is used if the true distribution is believed to be Gaussian and reference limits (percentiles) are determined as the values located 2 SDs less than and greater than the mean. Most parametric methods in fact are based on the Gaussian distribution. If the reference distribution has another shape, mathematical functions that transform data to approximately Gaussian shape may be used. In contrast, the **nonparametric** method makes no assumptions concerning the type of distribution and does not use estimates of distribution parameters. The percentiles are determined simply by cutting off the required percentage of values in each tail of the subset reference distribution.

When the results obtained by these two methods are compared, the estimates of the percentiles usually are very similar. In general, the simple and reliable nonparametric method is preferable to the parametric method.

POINTS TO REMEMBER

The preferred method to establish reference intervals is nonparametric analysis, which

- Requires 120 reference values per partition
- Can be applied to any distribution of values without transformation; specifically, does not require a Gaussian distribution, as most other methods do
- Involves simple mathematical skills
- Is the method endorsed by CLSI and IFCC

TABLE 5.2 Nonparametric Confidence Intervals of Reference Limits^a

Sample Size	RANK NUMBERS	
	Lower	Upper
119–132	1	7
133–160	1	8

^aThe table shows the rank numbers of the 0.90 confidence interval of the 2.5 percentile for samples with 119 to 500 values. To obtain the corresponding rank numbers of the 97.5 percentile, subtract the rank numbers in the table from $(n + 1)$, where n is the sample size.

From International Federation of Clinical Chemistry and Laboratory Medicine (IFCC), Expert Panel on Theory of Reference Values. Approved recommendation on the theory of reference values.

Nonparametric method. Several nonparametric methods are available, but those based on ranked data are simple and reliable and allow nonparametric estimation of the confidence intervals of the percentiles.

The steps in a nonparametric procedure are as follows:

1. Sort the n reference values in ascending order of magnitude, and rank the values. The minimum value has rank number 1, the next value number 2, and so on, until the maximum value, rank n , is reached. Consecutive rank numbers should be given to two or more values that are equal ("ties"). Spreadsheet software such as EXCEL is often used to sort and rank this type of data.
2. Compute the rank numbers of the 2.5 and 97.5 percentiles as $0.025(n + 1)$ and $0.975(n + 1)$, respectively.
3. Determine the percentiles by finding the original reference values that correspond to the computed rank numbers, provided that the rank numbers are integers. Otherwise, interpolation between the two limiting values is necessary.
4. Finally, determine the confidence interval of each percentile by using the binomial distribution. Table 5.2 facilitates this step for the 0.90 confidence interval of 2.5 and 97.5 percentiles. The bounding rank numbers for each percentile may be located in the table.

Tables 5.3A and 5.3B show an example of the nonparametric determination of percentiles using the serum GGT values shown in Fig. 5.1.

GGT, γ -Glutamyltransferase.

Parametric method. The parametric method is more complicated than the nonparametric method and usually requires the use of a computer statistics program when large data sets are processed. The parametric method assumes that the true distribution is Gaussian. Therefore it is absolutely critical to test the goodness-of-fit level of the reference distribution to a hypothetical Gaussian distribution. A simple test is examination of the cumulative frequency plotted on Gaussian probability paper (Fig. 5.2B); the plot should be close to a straight line if the distribution is Gaussian. In addition, many statistical computer programs have goodness-of-fit tests (e.g., tests based on coefficients of skewness and kurtosis, the Kolmogorov-Smirnov test, the Anderson-Darling test).

If the reference distribution does not differ significantly from the Gaussian distribution, the 2.5 and 97.5 percentiles are estimated by values approximately 2 SDs on each side of the mean or more precisely:

$$2.5 \text{ Percentile } \bar{x} - 1.96 \times \text{SD}$$

TABLE 5.3B Nonparametric Determination of Reference Interval^a**Calculation of Rank Numbers of Percentiles**

Lower	0.025 (123 + 1) = 3.1 (i.e., Rank #3)
Upper	0.975 (123 + 1) = 120.9 (i.e., Rank #121)

Original Values Corresponding to These Rank Numbers

Lower limit (2.5 percentile)	7 IU/L
Upper limit (97.5 percentile)	47 IU/L

Rank Numbers and Values of the 0.90 Confidence Limits**Lower Reference Limits**

Rank numbers (see Table 5.2)	#1 and #7
Values	6 and 8 IU/L

Upper Reference Limits

Rank numbers (see Table 5.2)	(123 + 1) - 7 = #117 and (123 + 1) - 1 = #123
Values	39 and 50 IU/L

Summary

Lower reference limit	7 (6–8) IU/L
Upper reference limit	47 (39–50) IU/L

^aThe table shows an example using the γ -glutamyltransferase (GGT) results listed in Table 5.3A.

$$97.5 \text{ Percentile } \bar{x} + 1.96 \times \text{SD}$$

The 0.90 confidence interval of each percentile is estimated by the following two limits:

$$\text{Lower confidence limit} = \text{percentile limit} - 2.81 \times \frac{\text{SD}}{\sqrt{n}}$$

$$\text{Upper confidence limit} = \text{percentile limit} + 2.81 \times \frac{\text{SD}}{\sqrt{n}}$$

If the reference distribution is non-Gaussian, mathematical transformation of data may adjust the shape to approximate the Gaussian distribution. One frequent observation of interest is that logarithmically transformed values of a distribution with a long right tail (positively skewed) fit the Gaussian distribution rather closely (see Fig. 5.2D). In other cases, square roots of the values better approximate the Gaussian distribution. This information provides the basis for the common use of logarithmic and square root transformations when reference limits are estimated, as described in the following section. If these two functions fail to transform data to fit a Gaussian distribution, more general transformations can be used. Such functions are described in other relevant literature.

To apply the parametric procedure to transformed data, the process is very similar, as shown in the following steps:

1. Transform data with the logarithmic function $y = \log_{10}(x)$ (or $y = \ln[x]$) or by using square roots: $y = \sqrt{x}$. Then test the fit to the Gaussian distribution by using the methods described previously. If both transformations fail, then more general functions, which usually are more

Fig. 5.2 Distribution of 123 remaining γ -glutamyltransferase (GGT) values from reference subjects. (A) A histogram of the original, untransformed data. (B) The cumulative frequency of the data from (A) plotted on Gaussian probability paper. (C) A histogram of the logarithmic transformed data. (D) The cumulative frequency of the data from (C), plotted on Gaussian probability paper.

complicated, or the simple nonparametric method previously described should be used.

2. Then compute the *mean* ($\bar{y}$) and the standard deviation (SD_y) of the transformed data.
3. Next, estimate the percentiles and their confidence intervals in the transformed scale by using the formulas presented previously, substituting $\bar{y}$ for $\bar{x}$ and SD_y for SD .

TABLE 5.4 Summary of Glutamyltransferase Reference Interval Determination by Three Methods

Method	Lower Limit (Confidence Interval)	Upper Limit (Confidence Interval)	Values Below Lower Limit	Values Above Upper Limit
Nonparametric	7 (6–8)	47 (39–50)	1	2
Parametric-untransformed data	0 (–2 to 2)	36 (34–38)	0	7
Parametric-transformed data	7 (6–8)	40 (35–44)	1	6

The table summarizes the 95% reference intervals and associated 90% confidence limits generated by each of three methods for the same data set. The numbers of observed values deemed lower and higher than the corresponding interval for each method are given in the last two columns. Because the original data are positively skewed, note that the parametric techniques generate intervals that are biased low. Note too that the parametric technique on untransformed data has a lower confidence interval, which is actually less than 0.

4. Finally, reconvert the percentiles and their confidence intervals to the original data scale by using inverse functions—antilogarithms or squares, respectively.

As shown in Fig. 5.2D, the mean and the SD of the serum GGT values in Fig. 5.1 after logarithmic ($\log_{10}$) transformation are $\bar{y} = 1.212$ and $SD_y = 0.193$. The 2.5 percentile is:

$$1.212 - 1.96 \times 0.193 = 0.835$$

$$2.5 \text{ percentile} = 10^{0.835} = 6.84$$

The lower reference limit of serum GGT thus is 7 IU/L. The 0.90 confidence interval of this percentile is:

$$1.212 - 2.81 \times (0.193/\sqrt{123}) = 0.786$$

$$\text{Lower confidence limit} = 10^{0.786} = 6.1$$

$$1.212 + 2.81 \times (0.193/\sqrt{123}) = 0.884$$

$$\text{Upper confidence limit} = 10^{0.884} = 7.7$$

that is, 6 to 8 IU/L. The 97.5 percentile (and its 0.90 confidence interval) is by the same method found to be 40 IU/L (35 to 44 IU/L).

Table 5.4 demonstrates that the nonparametric method and the parametric method (using the transformed data) result in very similar estimates of reference limits (percentiles).

Other methods for calculating reference limits. Other methods have been recommended for calculating reference limits, including the so-called bootstrap and robust methods. Neither of these methods makes assumptions about the underlying distribution; it needs not be Gaussian. Both require the use of computer software because they involve numerous iterations and somewhat complicated calculations. A brief discussion of these two methods is available elsewhere.

USE OF REFERENCE VALUES

In practice, interpreting medical laboratory data requires comparison of the patient's values with reference values.

Presentation of an Observed Value in Relation to Reference Values

An observed value (patient's value) may be compared with reference values. This comparison is often similar to hypothesis testing, but it is seldom statistical testing in the strict sense. Thus it is advisable to consider the reference values as the yardstick for a less formal assessment than hypothesis testing.

The clinician or health care provider should be supplied with as much information about the reference values as necessary for the interpretation. Reference intervals for all laboratory tests may be presented to clinicians or health care providers in a booklet, together with information about the analysis methods and their imprecision, along with descriptions of the reference values. A convenient presentation of the observed value and the reference interval on the same report sheet can be helpful to the busy clinician or health care provider. For example, the reference intervals may be pre-printed on report forms, or the computer system may select the appropriate age- and sex-specific reference interval from the database and print it next to the test result or in graphical form. In some countries, there are specific recommendations for the uniform formatting of laboratory reports.

An observed value may be classified as low, usual, or high, depending on its location in relation to the reference interval. On reports, a convenient practice is to flag unusual results (e.g., through use of the letters *L* and *H* for low and high, respectively).

Another popular method of classification is expressing the observed value by a mathematical distance measure. For example, the well-known SD unit, or normal equivalent deviation, is such a measure. It is calculated as the difference between the observed value and the mean of the reference values divided by their SD. However, this measure is unreliable if the distribution of values is skewed. Values beyond approximately 2 SD imply that the value is beyond the central 95% of the reference interval. Indeed, by using the SD

Fig. 5.3 The relationship between population-based and subject-based reference distributions and reference intervals. The example is hypothetical, and the two distributions are, for simplicity, Gaussian. Hypothetical means and standard deviations are μ and σ (for the population) and μ_i and σ_i (individual, i). (Modified from Harris, E. K. [1974]. Effects of intra- and interindividual variation on the appropriate use of normal ranges. *Clinical Chemistry*, 20, 1536.)

unit deviation value, one determines the percentile of the observed value (e.g., values greater than 3.0 SD occur in only less than 0.15% of people in the reference distribution).

Subject-Based Reference Values

Fig. 5.3 illustrates the inherent problem associated with **population-based reference values**. The figure shows two hypothetical reference distributions. One represents the common reference distribution based on single samples obtained from a group of several different reference individuals. It has a true (hypothetical) mean μ and an SD of σ . The other distribution is based on several samples collected over time in a single individual, the i th individual. Its hypothetical mean is μ_i and the SD, σ_i .

If an observed value is located outside the subject's 2.5 and 97.5 percentiles (i.e., the personal or **subject-based reference interval**), the cause may be a change in biochemical status, suggesting the presence of disease. Fig. 5.3 demonstrates that such an observed value still may be within the population-based reference interval. The sensitivity of the latter interval to changes in a subject's biochemical status depends accordingly on the location of the individual's mean μ_i relative to the common mean μ and to the relative magnitudes of the corresponding SDs, σ_i and σ . A mean μ_i close to μ and a small σ_i relative to σ may conceal the individual's changes entirely within the population-based reference interval.

Two specific examples may help to clarify this concept. Fig. 5.4 depicts immunoglobulin M (IgM) values from several healthy individuals over the course of several days. As illustrated, intraindividual differences are small as compared with interindividual differences. Even though the population-based reference interval might extend from 200 to 1600 mg/L, in practice it would be unusual (abnormal) for any patient's IgM value to change by more than 200 mg/L, even if the value remained within the population-based

Fig. 5.4 Serial immunoglobulin M (IgM) values over several days from reference individuals. Note that intraindividual variability is very small compared with interindividual variability. (From Statland, B. E., Winkel, P., Killingsworth, L. M. [1976]. Factors contributing to intra-individual variation of serum constituents: 6. Physiological day-to-day variation in concentrations of 10 specific proteins in sera. *Clinical Chemistry*, 22, 1635–1636.)

reference interval. Similarly, it is well known that any given patient's serum creatinine value is reasonably constant, and this is related both to glomerular filtration rate (GFR) and to lean muscle mass. If the latter is constant, changes in GFR are inversely proportional to the serum creatinine (see [Chapters 21 and 35](#)), that is, even though a typical (population-based) reference interval for serum creatinine might extend from 62 to 106 $\mu\text{mol/L}$ (0.7 to 1.2 mg/dL), a change from 65 to 105 $\mu\text{mol/L}$ in a given patient would be distinctly abnormal, representing loss of almost half of the GFR.

At least one solution is known for the problem of the limitations of population-based reference intervals for certain tests. With this solution, the subject's previous values, obtained in a well-defined state of health, are used as the reference for any future value. Application of subject-based reference values becomes more feasible as "health screening" by laboratory tests and computer storage of results become available to large sections of the general population.

Transferability of Reference Values

Determining reliable reference values for each test in the laboratory's repertoire is a major task that is often far beyond the capabilities of the individual laboratory. Therefore it would be convenient if reference values generated in another laboratory could be used. This is especially important when ethical considerations limit the number of available individuals (e.g., when pediatric reference values are produced). Then cooperative establishment of reference values may be necessary.

A major prerequisite for transfer of reference values is that the populations must be comparable, and no major ethnic, social, or environmental differences must be noted between them. If they are not comparable, a separate reference interval study must be done.

Other factors that should not be overlooked include adherence to explicit, standardized protocols for (1) qualifying reference individuals, (2) preparing those individuals for specimen collection, and (3) performing specimen collection.

Analytical Issues

In practice, even if the populations are comparable and preanalytical standards are met, the problem of analytical **transferability** remains. The optimal, but usually very unrealistic, situation assumes that analytical methods, including their calibration and quality assurance, are identical in the laboratories. A more pragmatic approach involves (1) standardization of analytical protocols, (2) common calibration, (3) design of a sufficiently efficient external quality control scheme, and (4) the use of mathematical transfer functions if results still are not directly comparable.

Other Sources for Reference Limits

Sources for reference limits include manufacturers' package inserts, peer-reviewed publications, and multicenter trials. An advantage of using manufacturers' package inserts is that the analytical issues just mentioned are largely addressed. However, comparability of the patient populations and of other preanalytical issues must be ensured. For example, the creatine kinase (CK) upper reference limits cited in a package insert based on a Caucasian population underestimated, by several fold, the upper reference limits for blacks and Asians.

As to peer-reviewed publications, when a laboratory considers adopting such reference limits, both method and population comparability must be addressed, but these tasks may be considerably easier for the laboratory than performing its own reference interval study. For example, the CALIPER initiative established, using the techniques described earlier, pediatric reference intervals, partitioned by age, sex, and ethnicity, for 40 different assays. As the authors emphasized, the published reference limits were specific to the methods they used.

A third source for reference limits is becoming increasingly popular—multicenter trials. In contrast to the CALIPER initiative, in which all the analyses were performed by a single laboratory, these studies seek to pool data from many laboratories spread over large regions and potentially among different countries. Although this decreases the number of reference individuals needed to be recruited from each laboratory, it also typically increases the number of analytical methods involved for each assay. Despite global efforts at harmonization and standardization, these multicenter trials have repeatedly shown that current methods do not always produce interchangeable results, and therefore methods to ensure method comparability are still needed.

Verification of Transfer

Whether a laboratory adopts reference values from (1) a package insert, (2) another laboratory, or (3) a multicenter trial, it is important that the laboratory verifies the appropriateness of those values for its own use. This verification serves as the final check that the laboratory has implemented the analytical method correctly and that the laboratory's own population is comparable with that used for the original reference value study.

Comparison of a locally produced, small subset of values with the large set produced elsewhere using traditional statistical tests often is not appropriate because the underlying statistical assumptions are not fulfilled and the sample sizes are unbalanced. A reasonably practical alternative has been recommended by the Clinical and Laboratory Standards Institute (CLSI): With a sample size of 20 reference values, one verifies the appropriateness of a proposed reference interval as long as no more than two values are outside the proposed limits.

POINTS TO REMEMBER

Sources for reference limits (other than establishing one's own)

- Manufacturers' package inserts^a
- Peer-reviewed literature^a
- Multicenter trials^a

^aIn all cases the use of these outside sources should be confirmed by a (short) verification study. See text.

Process of Selecting Reference Limits

Laboratories are responsible for, and usually take the lead in, providing reference limits for their test results. However, there are many potentially complicated decisions involved in the process, and the final selection of reference limits will influence the decisions of many physicians about their patients. As a result a multidisciplinary group should be involved in making decisions, such as whether to perform a reference interval study or to transfer intervals from another source; if the decision is made to do a local study, whether partitioning will be necessary (which will affect the number of subjects) and which preanalytical variables are relevant; and if limits will be transferred from another source, whether the methods and populations from that source are comparable.

Clinical Sensitivity, Specificity, and Predictive Value

When a clinician or a health care provider uses a laboratory test to help establish a diagnosis (as opposed to following a trend or evaluating the effectiveness of treatment), knowing the test's sensitivity and specificity can assist with proper interpretation (see Chapter 2). The **clinical sensitivity** of an assay is the fraction of those subjects with a specific disease that the assay correctly detects. The **clinical specificity** is the fraction of those individuals without the disease that the assay correctly detects. Fig. 5.5A illustrates pertinent definitions and formulas.

Changing the decision limit of an assay affects both clinical sensitivity and specificity. Consider the case when the disease group has higher assay values than the healthy group (Fig. 5.6). Values greater than the decision limit are classified as positive; those at or less than are negative. Moving the upper decision limit to a lower value increases the clinical sensitivity—but at the cost of decreased clinical specificity. Thus increased true-positive detection is traded for an increase in the number of false-positive results. This trade-off occurs in most tests performed in medicine.

Formulas

A

	Patients with positive test result	Patients with negative test result	
Patients with disease	True positives (TP)	False negatives (FN)	<i>Clinical sensitivity</i> = $\frac{TP}{TP + FN}$
Patients without disease	False positives (FP)	True negatives (TN)	<i>Clinical specificity</i> = $\frac{TN}{FP + TN}$
	<i>Total positives</i> = $TP + FP$	<i>Total negatives</i> = $FN + TN$	
	<i>PV (positive test)</i> = $\frac{TP}{TP + FP}$	<i>PV (negative test)</i> = $\frac{TN}{(FN + TN)}$	

Test X: Disease prevalence = 50%

B

	Patients with positive test result	Patients with negative test result	
100	95	5	<i>Sensitivity</i> = $95/(95 + 5)=95\%$
100	10	90	<i>Specificity</i> = $90/(90 + 10)=90\%$
	<i>Positives</i> = $95 + 10=105$	<i>Negatives</i> = $5 + 90=95$	
	<i>PV (positive)</i> = $95/(95 + 10)=90\%$	<i>PV (negative)</i> = $90/(90 + 5)=95\%$	

Test X: Disease prevalence = 5%

C

	Patients with positive test result	Patients with negative test result	
500	475	25	<i>Sensitivity</i> = 95%
9500	950	8550	<i>Specificity</i> = 90%
	<i>Positives</i> = $475 + 950=1425$	<i>Negatives</i> = $25 + 8550=8575$	
	<i>PV (positive)</i> = $475/1425=33\%$	<i>PV (negative)</i> = $8550/8575=99.7\%$	

Fig. 5.5 (A) A basic 2 × 2 table (*bold lines*) facilitates understanding of the concepts of sensitivity, specificity, and predictive value. In the left-hand column, all patients with positive test results are tabulated; in the right-hand column, all patients with negative test results are tabulated. In the top row, patients with the disease under study are divided by their test results; likewise, the bottom row (*shading*) divides people without the disease by their test results. The top left-hand corner then represents patients with disease who have positive results, true positives. The other three boxes are as labeled. As shown, the clinical sensitivity is calculated using the top row; the clinical specificity is calculated using the bottom row. The predictive value of a positive test is calculated using the data in the left-hand column; the predictive value of a negative test, using the right-hand column. (B) The calculations described in A are done on test X, whose sensitivity and specificity are 95% and 90%, respectively. For this example, the prevalence of the population tested is 50%, reflected in the fact that 100 people with disease and 100 people without disease are tested. Of note, this is frequently the prevalence used when tests are first described in the literature. As shown, the predictive value of a positive test is 90%. (C) The same calculations are done on the same test X, but the prevalence used is a more realistic, but still quite high, 5%, reflected in the fact that 500 people have the disease and 9500 do not. Although the sensitivity and specificity remain unchanged (95% and 90%, respectively), the predictive value of a positive test is now just 33%, that is, the likelihood that a patient with a positive test result in this population actually has the disease is 33%, or, in other words, 67% of the positive results are false positives.

Fig. 5.6 Simulated distributions of healthy and diseased populations. Note that at the shown decision threshold, the probability of a subject with disease (*a*) is much less than the probability of a healthy subject (*b*). FN, False negatives; FP, false positives; TN, true negatives; TP, true positives.

A separate, perhaps more important and more practical, issue that faces clinicians is this: Given a positive result, what is the likelihood that a patient actually has the disease? The **predictive value** of a positive test answers this question. The predictive value of a test combines disease prevalence with the test's sensitivity and specificity. **Prevalence** is the proportion of the population (or of those being tested) with the disease. The predictive value of a positive test is the number of true-positive results divided by the total number of positive results (true-positive and false-positive results combined). As reflected in Fig. 5.5B and C, the proportion of true-positive and false-positive results is a function of the prevalence in the population and of the sensitivity and specificity of the test in question.

As shown in Fig. 5.5A, the predictive value of a negative test follows in a similar way. It answers the question, "Given a negative result, how likely is it that a patient does not actually have the disease?" It has been used very effectively in many situations, for example, to reliably exclude, in the appropriate clinical context, deep venous thrombosis and/or pulmonary embolism.

When "Normal" May Appear to Be "Abnormal" and Vice Versa

Some, if not many, clinical laboratory test results are related to other clinical laboratory test results. For example, consider the relatively common situation of a patient with a low serum albumin. Because of the relationship between total calcium and albumin in serum (see Chapter 39), a total serum calcium concentration in the healthy reference interval might actually be pathologically high in this patient, and a total serum calcium concentration less than the lower reference limit might be healthy.

As another example, consider prostate-specific antigen (PSA) concentration in a post-prostatectomy patient or thyroglobulin in a post-thyroidectomy patient. In these cases, it would be "healthy" to have abnormally low (undetectable) concentrations of these measurands, and it would be distinctly abnormal to have "healthy" (detectable) levels. In these cases the problem is that the traditional reference population is not appropriate.

In other words, even when reference limit studies are done well, one needs to remember there are dependencies that can render those reference limits misleading.

REVIEW QUESTIONS

- A "subject-based" reference value is:
 - obtained from a group of systematically defined reference individuals.
 - the type of value referred to when the term *reference value* is used with no qualifying words.
 - based on several samples collected over time in a single individual.
 - a random sample of all individuals in the parent population who fulfill the selection criteria.
- True-negatives ÷ (false-positives + true-negatives) × 100 is the formula for determining:
 - clinical sensitivity.
 - clinical specificity.
 - predictive value.
 - reference value.
- The proportion of a population that has the particular disease being studied for establishment of reference values is referred to as the:
 - prevalence.
 - predictive value.
 - positive value.
 - clinical sensitivity.
- When reference values are established, the criteria used to determine which individuals should be included in the group of reference individuals are referred to as:
 - exclusion criteria.
 - inclusion criteria.
 - partition criteria.
 - selection criteria.
- Calculate the predictive value of a test in which 220 tested individuals with positive test results actually have the disease and 45 tested individuals with positive test results do not have the disease.
 - 16.9%
 - 66%
 - 83%
 - 120%
- An example of an exclusion criterion when establishing reference values would be a(n):
 - individual's age.
 - risk factor such as obesity.
 - individual's ethnic origin.
 - individual's sex.

7. In the selection of reference individuals, subclassifying a set of these individuals into homogeneous groups is referred to as:
 - a. partitioning.
 - b. excluding.
 - c. transferring.
 - d. including.
8. The number of true positive results divided by the sum of true positive results plus false positive results is referred to as:
 - a. clinical sensitivity of a positive result.
 - b. clinical specificity of a positive result.
 - c. prevalence of the disease.
 - d. predictive value of a positive result.
9. When reference limits are determined, the statistical method that assumes that the true distribution of reference values is a Gaussian (normal) distribution is the:
 - a. nonparametric method.
 - b. parametric method.
 - c. interpercentile interval method.
 - d. predictive value.

Specimen Collection, Processing, and Other Preanalytical Variables

Doris M. Haverstick, Patricia M. Jones

OBJECTIVES

- Define the following terms:
 - Anticoagulant
 - Controllable preanalytical variable
 - Hemolysis
 - Order of draw
 - Phlebotomy
 - Plasma
 - Preanalytical variable
 - Preanalytical error
 - Serum
 - Uncontrollable preanalytical variable
 - Venipuncture
- Give two examples of a preanalytical error and two examples of an uncontrollable preanalytical variable.
- List the types of biologic specimens that are analyzed in a clinical laboratory.
- Summarize the steps that are performed by a phlebotomist in obtaining a blood sample by venipuncture; state the preferred site of venous blood collection, including the practice used when an intravenous line is present.
- List the general effects on analytes caused by the following:
 - Pumping a fist before venipuncture
 - Stress
 - Collection order (first tube, second tube, etc.)
 - Time of collection related to diurnal variation
 - Prolonged venous occlusion with a tourniquet
 - Not filling collection tube completely
- Discuss order of draw for multiple blood specimens, including the order required for collecting multiple tubes of blood, color of stopper and associated additive, need for tube filling and inversion, and reason for filling tubes in a specific order.
- Describe the skin puncture collection technique, including methods of stimulating blood flow; state the reasons for collecting a specimen using skin puncture; and describe the collection procedure for obtaining a blood spot for molecular genetic testing.
- Explain the difference between serum and plasma.
- Compare the difference in composition, if any, between serum and plasma specimens of the following analytes:
 - Calcium
 - Cholesterol
 - Albumin
 - Creatinine
 - Total protein
 - Glucose
 - Potassium
- State how the following anticoagulants prevent blood from coagulating:
 - Heparin
 - EDTA
 - Citrate
 - Oxalate
 - Iodoacetate
- State the appropriate analytical situations for using evacuated tubes containing various additives; state reasons why blood collected in the same anticoagulants cannot be used for certain analyses.
- Describe the hemoglobin concentration at which hemolysis is observable in plasma; describe how hemolysis affects measurement of certain analytes and use of certain analytical procedures.
- List three types of urine specimens and their use in clinical analysis; list two methods of urine preservation and discuss the use of each.
- Outline the procedure for collecting a timed urine specimen.
- List the clinical chemistry analyses performed on the following specimen types and the collection procedure name, if any:
 - Feces
 - Cerebrospinal fluid (CSF)
 - Synovial fluid
 - Amniotic fluid
 - Chorionic villus
 - Pleural, pericardial, and ascitic fluids
 - Saliva
 - Buccal cells
 - Hair and nails
- Summarize each of the four aspects of specimen handling; discuss these in relation to specimen identification on various containers, centrifugation of blood samples, sample storage on ice/at -20°C /at 4°C , protection from light, and transport guidelines.

KEY WORDS AND DEFINITIONS

Additives Compounds added to biologic specimens to prevent them from clotting or to preserve the constituents of a specimen.

Anticoagulant Any substance that prevents blood from clotting.

Chorionic villus sampling A prenatal test to detect birth defects that is performed at an early stage of pregnancy and involves retrieval and examination of tissue from the chorionic villi. Also called *chorionic villus biopsy*.

Coagulation (clotting) The sequential process by which the multiple coagulation factors of blood interact in the coagulation cascade, resulting in formation of an insoluble fibrin clot.

Diurnal variation Variation that occurs in the amount of a substance during a 24-hour period.

Hemolysis Disruption of the red cell membrane causing release of hemoglobin and other components of red blood cells.

Phlebotomist One who practices phlebotomy; the individual drawing a specimen of blood.

Phlebotomy The puncture of a blood vessel to collect blood; literally, “the letting of blood in the treatment of disease.”

Plasma The noncellular component of anticoagulated whole blood; plasma contains clotting factors.

Preanalytical errors Factors that affect specimens before tests are performed and that can lead to error

if not controlled; they are classified as controllable or uncontrollable.

Preservative A substance or preparation added to a specimen to prevent changes in the constituents of a specimen.

Serum The watery portion of blood that remains after coagulation has occurred; it is obtained after centrifugation.

Sharps Any object which could readily puncture or cut the skin of an individual when encountered.

Sharps container A container designed for the disposal of sharps; required and regulated by the Occupational Safety and Health Administration (OSHA).

Skin puncture Collection of capillary blood usually from a pediatric patient by making a thin cut in the skin, usually at the heel of the foot.

Specimen A sample or portion of body fluid or tissue collected for examination, study, or analysis.

Venipuncture All of the steps involved in obtaining an appropriate and identified blood specimen from an individual's vein.

Venous occlusion Obstruction of the return of venous blood to the heart and distention of the veins; in phlebotomy, this is a temporary blockage caused by application of pressure, usually from a tourniquet.

Proper collection, processing, storage, and transport of common sample types used for diagnostic testing are critical to the provision of quality test results. Each step involved, as well as factors associated with the patient, can be the source of errors that cause inaccurate results. Minimizing these errors will result in more reliable information for use by health care professionals in providing quality patient care.

This chapter provides a review of the most common specimen types and discusses how they are (1) collected, (2) identified, (3) processed, (4) stored, and (5) transported. Differences between adult and pediatric collection are highlighted.

PATIENT IDENTIFICATION

Before any specimen is collected, the phlebotomist must confirm the identity of the patient using two or three items of identification (e.g., name, medical record number, date of birth). In specialized situations, such as paternity testing or other tests of medicolegal importance, establishment of a chain of custody for the specimen may require that additional patient identification, such as a photograph, be provided.

Identification must be an active process, with the patient stating his or her name and the phlebotomist verifying information either on the patient's wrist band or on the test requisition form or computer order. In the case of pediatric patients the parent or guardian should be present and be asked to actively provide identification of the child in a manner to prevent a yes or no answer from an often distracted parent, such as: “Please tell me the name of your child.”

TYPES OF SPECIMENS

Types of biologic **specimens** that are analyzed in clinical laboratories include (1) whole blood; (2) serum; (3) plasma; (4) urine; (5) feces; (6) saliva; (7) other body fluids such as spinal, synovial, amniotic, pleural, pericardial, and ascitic fluids; and (8) cells and various types of solid tissue. The World Health Organization and the Clinical and Laboratory Standards Institute (CLSI) have published several guidelines for collecting many different types of specimens under standardized conditions (Table 6.1).

Blood

Blood for analysis may be obtained from veins, arteries, or capillaries. Venous blood is usually the specimen of choice. Arterial puncture is used mainly for blood gas analyses. In young children and for many point-of-care tests, skin puncture is frequently used to obtain capillary blood. The process of collecting blood is known as **phlebotomy** (from *phleb*, which means vein, and *tome*, to cut or incise) and should always be performed by a trained **phlebotomist**.

Venipuncture

In the clinical laboratory, **venipuncture** is defined as all of the steps involved in obtaining an appropriate and identified blood specimen from a patient's vein (CLSI H3-A6, see Table 6.1).

Preliminary steps. Prior to collection, the patient should be asked about latex allergies, and if necessary the phlebotomist

should secure nonlatex equipment. Any signed consent forms or special requisitions should be completed.

Before collection, the phlebotomist should dress in personal protective equipment (PPE), such as an impervious gown and gloves. PPE and adherence to standard precautions limit the spread of infectious disease from one patient to another and promote the safety of the phlebotomist. PPE is often brightly colored in pediatric institutions, where small children may be frightened of anyone in a white coat or gown. When collecting specimens from a patient in isolation in a

hospital, the phlebotomist must often dress in specialized PPE. The extent of the precautions required varies with the nature of the patient's illness and the institution's policies and bloodborne pathogen plan.

If appropriate, the phlebotomist should verify that the patient has fasted, identify what medications are being taken or have been discontinued as required, and determine any other relevant information. The patient should be comfortable, seated or supine, and should have been in this position for as long as possible before the specimen is drawn. At no time should venipuncture be performed on a standing patient.

Infants and young children may need to be held to prevent movement. A young child may be held sitting upright in a parent's lap, with the parent helping to support and hold the patient and arm still (Fig. 6.1). An infant's blood is often drawn with the infant in a supine position, and the infant may be swaddled in a blanket, or a papoose board may be used to restrain movement.

Either of the patient's arms should be extended in a straight line from the shoulder to the wrist. An arm with extensive scarring or a hematoma at the intended collection site should be avoided. If a woman has had a mastectomy, arm veins on that side of the body should not be used. If a woman has had double mastectomies within 6 months, a vein on the back of the hand or ankle should be used. Outside of 6 months, blood should be drawn from the arm of the side on which the first procedure was performed.

Before performing a venipuncture, the phlebotomist should estimate the volume of blood to be drawn and select the appropriate number and types of tubes for the tests requested. This may be facilitated by computer-generated collection recommendations and should be designed to collect the minimum amount necessary for testing. Estimating volume of blood to be drawn is especially critical in a pediatric setting. Because an average-weight newborn infant has a total blood volume of approximately 350 mL, blood collection in the pediatric population should not exceed recommended volumes for the pediatric patient's weight. Iatrogenic blood loss can lead to unnecessary blood transfusions and increased risk of exposure to bloodborne pathogens.

Fig. 6.1 Holding a child for venipuncture. (Modified from World Health Organization. [2010]. WHO guidelines on drawing blood: best practices in phlebotomy. *Pediatric and Neonatal Blood Sampling*. Geneva: World Health Organization. <http://www.ncbi.nlm.nih.gov/books/NBK138647>.)

In addition to tubes, an appropriate needle must be selected. The most commonly used sizes for adults are 19 to 22 gauge. (The larger the gauge number, the smaller the bore.) The usual choice for an adult with normal veins is 20 gauge. In pediatric patients, 23- to 25-gauge needles are most commonly used, with 23-gauge being the preferred size because infant veins are very small. Even for larger volumes of blood, rarely will a needle larger than a 21 gauge be used because it will not fit into the vein easily. A needle is typically 1.5 inches (3.7 cm) long, but 1-inch (2.5-cm) needles, usually attached to a winged or butterfly collection set, are also commonly used in pediatrics and geriatrics. Finally, the phlebotomist should ensure that all post-draw safety devices are in place, including convenient and safe access to proper disposal devices for contaminated needles and associated devices and appropriate post-blood draw supplies (gauze and bandage).

Location. The median cubital vein in the antecubital fossa, or crook of the elbow, is the preferred site for collecting venous blood in adults because the vein is large and close to the surface of the skin. Veins on the back of the hand or at the ankle may be used, although these should be avoided in people with diabetes or with poor circulation. However, in infants and children younger than 2 years old, collection from superficial veins is recommended, and dorsal hand veins are preferred over the median cubital vein. An arm containing a cannula or an arteriovenous fistula should not be used without consent of the patient's physician.

Preparation of the site. The area around the intended puncture site should be cleaned with institutionally approved cleanser. Commonly used materials are a prepackaged alcohol swab, a gauze pad saturated with 70% isopropanol, or a benzalkonium chloride solution. Cleaning of the puncture site should be done with a circular motion from the site outward. The skin should be allowed to dry in the air. No alcohol or cleanser should remain on the skin because traces may increase patient discomfort and cause hemolysis and invalidate test results.

Timing. The time at which a specimen is obtained is important for blood constituents that undergo marked **diurnal variation** (e.g., corticosteroids, iron), those for which a fasting sample has been requested, and those used to monitor drug therapy. In each case the timing should match the conditions under which reference intervals or clinical decision points were determined. Furthermore, timing is important in relation to specimens for alcohol or drug measurements in association with medicolegal considerations.

Venous occlusion. After the skin is cleaned, a blood pressure cuff or a tourniquet is applied 4 to 6 inches (10 to 15 cm) above the intended puncture site for adults. This obstructs the return of venous blood to the heart and distends the veins (**venous occlusion**). When a blood pressure cuff is used, it is usually inflated to approximately 60 mm Hg (8.0 kPa). If a dorsal hand vein is being accessed, no tourniquet is used. The phlebotomist applies enough pressure with the hand holding the patient's wrist and hand to occlude and distend the vein.

It is rarely necessary to leave a tourniquet in place for longer than 1 minute after venous access is secured, but even within

this short time, the composition of blood changes. Although the changes that occur in 1 minute are slight, marked changes have been observed after 3 minutes for some chemistry analytes. The composition of blood drawn first is most representative of the composition of circulating blood and the least affected by fluid shifts where protein-bound components and other large molecules will be concentrated; water-soluble smaller molecules such as electrolytes may be less affected. The first-drawn specimen should therefore be used for analytes such as calcium and other analytes that are both protein bound and pertinent to critical medical decisions. A uniform procedure for the order of draw for tests should therefore be established (see later). If it is possible to collect only a small volume of blood, the priority of which tests to perform should be established in consultation with the ordering physician.

Two special notes on the collection process: (1) Pumping of the fist before venipuncture should be avoided because it causes an increase in plasma potassium, phosphate, and lactate concentrations. Increased lactate lowers blood pH and causes the plasma ionized calcium concentration to increase. (2) The stress associated with blood collection can have effects on patients at any age. Thus plasma concentrations of analytes affected by stress, such as cortisol, thyroid-stimulating hormone, and growth hormone, may increase. Stress occurs particularly in young children who are frightened, struggling, and held in physical restraint. Collection under these conditions may cause adrenal stimulation, leading to an increased plasma glucose concentration, or may create increases in the serum activities of enzymes that originate in skeletal muscle.

Order of draw for multiple blood specimens. In a few patients, backflow from blood tubes into veins occurs owing to a decrease in venous pressure but can be minimized if the arm is held downward. When collecting multiple specimens with an evacuated tube system, one of the primary concerns is to prevent cross-contamination between tubes. To minimize these and other problems, blood should be collected into tubes in the order outlined in [Table 6.2](#).

Collection with evacuated blood tubes. Evacuated blood tubes are usually considered to be safer, less expensive, more convenient, and easier to use than syringes. Tubes vary by the type of **additive** and the volume of the tube. The different types of additives are identified by the color of the stopper used. Color coding of specimen collection tubes is not yet harmonized and may vary according to manufacturers (CLSI H1-A5, see [Table 6.1](#)). Serum or plasma separator tubes are available that contain an inert, polymer gel material that settles like a disk between cells and supernatant when the tube is centrifuged. Release of intracellular components into the supernatant is thus generally prevented. Most importantly, these separator tubes may be used as primary containers from which serum or plasma can be directly aspirated by a number of analytical instruments, avoiding aspiration of red blood cells (RBCs) or possible errors of patient or sample identification during aliquoting. Increasingly, tubes are sold for special applications, such as RNA isolation. As with all specimen collection containers, these less common tubes must be validated by each laboratory before use if not approved by the manufacturer for the specific analysis to be conducted.

TABLE 6.2 Recommended Order of Draw for Multiple Specimen Collection

Stopper Color	Contents	Inversions
Yellow	Sterile media for blood culture	8
Royal blue	No additive	0
Clear	Nonadditive; discard tube if no royal blue used	0
Light blue	Sodium citrate	3–4
Gold/red	Serum separator tube	5
Red/red, orange/ yellow, royal blue	Serum tube, with or without clot activator, with or without gel	5
Green	Heparin tube with or without gel	8
Tan (glass)	Sodium heparin	8
Royal blue	Sodium heparin, sodium EDTA (trace metal free)	8
Lavender, pearl white, pink/pink, tan (plastic)	EDTA tubes, with or without gel	8
Gray	Glycolytic inhibitor	8
Yellow (glass)	ACD for molecular studies and cell culture	8

ACD, Acid citrate dextrose; EDTA, ethylenediaminetetraacetic acid. Modified from information in Clinical and Laboratory Standards Institute. (2003). *Tubes and additives for venous blood specimen collection: CLSI-approved standard H1-A5* (5th ed.). Wayne: Clinical and Laboratory Standards Institute; and Kiechle, F. L. (Ed.), (2005). *So you're going to collect a blood specimen: an introduction to phlebotomy* (11th ed.). Northfield: College of American Pathologists.

Blood collected into a tube containing one additive should never be transferred into other tubes because the first additive may interfere with tests for which a different additive is specified. For example, ethylenediaminetetraacetic acid (EDTA) contamination can cause an erroneously reported hyperkalemia or hypocalcemia when an inappropriate tube type is analyzed.

After the skin has been cleaned, the needle is guided gently into the patient's vein; when the needle is in place, the tube is pressed forward into the holder to puncture the stopper and release the vacuum. As soon as blood begins to flow into the tube, the tourniquet is released without moving the needle. The tube is filled until the vacuum is exhausted. It is critically important that the evacuated tube be filled completely. Many additives, particularly for coagulation testing, are provided at concentrations in the tube based on a "full and proper" collection; both short and too-full draws can be a source of **preanalytical error** because they can significantly affect the established testing parameters that are based on a properly collected sample. Vacuum tubes should never be opened and filled from a syringe or other source.

Blood collection with a syringe. Syringes are customarily used for patients with difficult veins and for blood gas analysis. The syringe with the needle attached should be aligned with the vein to be entered and the needle pushed into the vein with the bevel up and at an angle to the skin

of approximately 15 degrees. When the initial resistance of the vein wall is overcome, forward pressure on the syringe is eased, and the blood is withdrawn by very gently pulling back the plunger of the syringe.

After filling the syringe and completing the collection, if the sample needs to be transferred to an evacuated tube, the same needle, a new needle, or a transfer device should be used to puncture the cap of the tube. The tube should be allowed to fill passively using its vacuum. Vigorous withdrawal of blood into a syringe during collection or forceful transfer from the syringe to the receiving vessel may cause hemolysis of blood, making the sample invalid for testing.

Completion of collection. When blood collection is complete and the needle withdrawn, a dry gauze pad should be held tightly over the puncture site with the arm raised to stop residual bleeding and promote the clotting process; the pad can be held in place firmly by a bandage or by a nonadhesive strap. The needle is covered, and the needle and the tube holder are immediately discarded into a **sharps container**. In the event that a winged (butterfly) set is used, the wings are either pushed forward to cover the needle or a button is pressed to a spring that retracts the needle. All used supplies should be discarded in a hazardous waste receptacle.

Tubes should then be labeled per institutional policy. Most institutions have a written procedure prohibiting the advance labeling of tubes because of the potential for mislabeling, one of the most common sources of preanalytical error. Many US institutions recommend showing the labeled tube to the patient to further confirm correct identification.

Venipuncture in children. The techniques for venipuncture in children and adults are similar. However, children are likely to make unexpected movements, and assistance in holding them still is often desirable. Although a syringe or an evacuated blood tube system may be used to collect specimens, a syringe with a winged butterfly collection set is more commonly used in younger children. The pressure on a syringe can be more easily controlled by the phlebotomist than the vacuum pressure in an evacuated tube, thus preventing the pressure from pulling small veins closed. In the pediatric population, alternative collection through skin puncture is often used.

Skin Puncture

Skin puncture is an open collection technique in which the skin is punctured by a lancet and a small volume of blood is collected into a microdevice. In practice, skin puncture is used in situations in which (1) sample volume is limited (e.g., pediatric applications), (2) repeated venipunctures have resulted in severe vein damage, or (3) patients have been burned or bandaged and veins therefore are unavailable for venipuncture. This technique is also commonly used when the sample is to be applied directly to a testing device in a point-of-care testing situation or to filter paper. It is most often performed on the tip of the finger or the heels of infants. In an infant younger than 6 months, the lateral or medial plantar surface of the foot should be used for skin puncture (Fig. 6.2). These areas are the fleshiest part of the foot in an infant, with the

Fig. 6.2 Acceptable sites for skin puncture to collect blood from an infant's foot. (Modified from Blumenfeld, T. A., Turi, G. K., & Blanc, W. A. [1979]. Recommended site and depth of newborn heel punctures based on anatomical measurements and histopathology. *Lancet*, 1, 230–233. Reprinted with permission from Elsevier.)

TABLE 6.3 Tip Lengths in Finger- and Heel-Stick Devices

Collection Type and Age of Use	Tip Length (mm)
Heel stick: premature infants	0.85
Heel stick: term infants to 6 months old	1.25
Heel stick: 6 months to 1 year	1.25
Finger stick: walking to 8 years	1.5
Finger stick: >8 years	1.75–2.2

most distance between the skin surface and the underlying bone, decreasing the risk of inadvertently hitting bone and causing a bone infection. The back of the heel and the toes should not be used. Blood collection from anywhere on the foot should be avoided on ambulatory patients; thus, when an infant starts walking, a heel stick should no longer be performed. Lancets are made specifically for a heel stick or a finger stick, and they should not be used interchangeably because they have different tip lengths (Table 6.3). The finger-stick procedure should not be performed on infants younger than 6 months because no commercially available device punctures shallow enough to avoid bones. The complete procedure for collecting blood from infants using skin puncture is described in CLSI H04-A6 (see Table 6.1).

To collect by skin puncture, the phlebotomist first cleans the skin with an approved cleaning solution; once the skin is dry, it is quickly punctured by a sharp stab with a lancet. To minimize the possibility of infection, a different site should be selected for each puncture. The finger should be held in such a way that gravity assists collection of blood at the fingertip and the lancet held to make the incision as close to perpendicular to the fingernail as possible. Massage of the finger to stimulate blood flow should be avoided because it causes the outflow of debris and tissue fluid, which does not have the same composition as plasma. To improve circulation of the blood, the finger or heel may be warmed by application of a warm, wet washcloth or a specialized device, such as a heel warmer, for 3 minutes before cleaning and the lancet is applied. Warming properly will not only cause the capillary blood to be free flowing and improve the ability to collect the sample, but the analytes in the sample will also approach arterial blood values. In a cold heel, the values more approximate

TABLE 6.4 Order of Draw for Skin Puncture: Capillary Blood

Usage or Additive	Tube Top Color
Blood gases (heparin)	Microhematocrit tubes
Ethylenediaminetetraacetic acid	Lavender
Heparin	Green
Other additives	Light blue, gray
Nonadditives	Red, tiger, yellow

venous blood. The first drop of blood is wiped off, and subsequent drops are transferred to the appropriate collection tube by gentle contact. Filling should be done rapidly to prevent clotting, and introduction of air bubbles should be prevented.

A variety of collection tubes are commercially available for capillary blood collection. Samples should be collected by dripping or capillary action from the puncture site into the small tubes. Drop-by-drop collection and scooping along the skin with the edge of the tube should be avoided because both practices increase hemolysis. The correct order of filling of these devices differs from evacuated blood tubes because the concerns are different. The anticoagulant tubes, especially the EDTA tube for the complete blood count (CBC), are collected first rather than last. The serum tubes are collected last (Table 6.4).

For collection of blood specimens on filter paper for molecular genetic testing and neonatal screening (CLSI LA4-A5, see Table 6.1), the skin is cleaned and punctured as described previously. The first drop of blood is wiped away and the filter paper is gently touched against a large drop of blood that is allowed to soak into the paper to fill the marked circle. Only a single application per circle should be made. The procedure is repeated to fill all the circles. The filter paper should be properly labeled and then air-dried for 2 to 3 hours before storage in a labeled paper envelope.

Arterial Puncture

Arterial puncture requires considerable skill and is usually performed only by physicians or specially trained personnel. Preferred sites of arterial puncture are, in order, the (1) radial artery at the wrist, (2) brachial artery in the elbow, and (3) femoral artery in the groin, with sites in the arm used most often. The proper technique for arterial puncture is described in CLSI H11-A4 (see Table 6.1).

Anticoagulants and Preservatives for Blood

Serum is defined as that portion of blood that remains after **coagulation** has occurred and the cells have been removed and is the specimen of choice for many analyses. Samples are collected into tubes with no additive or with a clot activator and must be allowed to complete the coagulation process before further processing. **Plasma** is defined as the noncellular component of anticoagulated whole blood after the cellular components have been removed. Heparinized plasma is increasingly being used for routine chemistry testing to decrease turnaround time because it is not necessary to wait for the blood to clot. However, considerable differences may be observed between the concentrations of certain analytes

(such as total protein) in serum and in plasma. For molecular diagnostics, anticoagulated whole blood or plasma is more likely to be the specimen of choice for either genomic DNA isolation from the white blood cells (WBCs) or viral identification and quantification from plasma.

For any assay provided for clinical use, manufacturers specify the appropriate sample type(s) for which they have validated the assay. Use of different sample types must be validated by laboratory personnel before use.

Heparin. Heparin is the most widely used **anticoagulant** for chemistry testing. It is available as sodium, potassium, lithium, and ammonium salts, all of which can adequately prevent coagulation by accelerating the action of antithrombin III, which neutralizes thrombin. This prevents the formation of fibrin from fibrinogen. Heparin is a naturally occurring anticoagulant and has the disadvantages of high cost and a more temporary action of anticoagulation than is attained by the chemicals discussed later. The use of lithium or ammonium heparin is unacceptable for lithium and ammonia measurements, respectively.

It should be noted that heparin is unacceptable for most tests performed using polymerase chain reaction (PCR) because of inhibition of the polymerase enzyme by this large molecule. DNA can be extracted from heparinized samples, but amplification may be reduced, and the effect of heparin on any molecular diagnostic assay should be assessed as part of a method validation study.

Ethylenediaminetetraacetic acid. EDTA is a chelating agent of divalent cations such as Ca^{2+} and Mg^{2+} that is particularly useful for (1) hematologic examinations including transfusion medicine applications, (2) measurement of intracellular drugs such as cyclosporine or tacrolimus, (3) HbA_{1c} analysis, (4) isolation of genomic DNA, and (5) qualitative and quantitative virus determinations by molecular techniques. It is used most commonly as the tripotassium salt. EDTA prevents coagulation by binding calcium, which is essential for the clotting mechanism.

Because it chelates calcium, magnesium, and iron, EDTA is unsuitable for specimens for these analyses. In addition, EDTA, probably by chelation of required metallic cofactors, inhibits alkaline phosphatase and creatine kinase activities.

Sodium fluoride. Sodium fluoride (NaF) is a weak anticoagulant that is often added as a preservative for blood glucose and lactate. As a preservative, it is often used together with another anticoagulant such as potassium oxalate. It exerts its **preservative** action by inhibiting the enzyme systems involved in glycolysis, although such inhibition is not immediate, and a certain amount of degradation occurs during the first hour after collection. Without an antiglycolytic agent, the blood glucose concentration decreases approximately 100 mg/L (0.56 mmol/L) per hour at 25°C. The rate of decrease is faster in newborns because of the increased metabolic activity of their erythrocytes and in leukemic patients because of the high metabolic activity and number of the WBCs. Because of the delay in onset of action, recent protocols recommend placing the tube on ice until the sample can be separated to ensure

accurate glucose measurements. Newer formulations containing both NaF and citrate or EDTA immediately inhibit glycolysis and preserve glucose in the specimen for at least 24 hours.

Citrate. Sodium citrate solution, in a ratio of 1 part to 9 parts of blood, is widely used for coagulation studies. The correct ratio of blood to anticoagulant is critical to achieve proper coagulation measurements because the anticoagulant effect is reversed by addition of standard amounts of Ca^{2+} that are based on a proper collection volume. Because citrate chelates calcium, it is unsuitable as an anticoagulant for specimens for measurement of this element. It also inhibits aminotransferases and alkaline phosphatase but stimulates acid phosphatase when phenylphosphate is used as a substrate.

Acid citrate dextrose. When both the form and function of the cellular components are required, such as for cytogenetic testing, samples are generally collected into acid citrate dextrose (ACD) anticoagulant. There are two ACD tube designations: ACD A and ACD B. These differ only by the concentrations of the additives. Both enhance the vitality and recovery of WBCs for several days after collection of the specimen.

Oxalates. Sodium, potassium, ammonium, and lithium oxalates inhibit blood coagulation by forming rather insoluble complexes with calcium ions.

Oxalate inhibits several enzymes, including acid and alkaline phosphatases, amylase, and lactate dehydrogenase (LDH), and may cause precipitation of calcium as the oxalate salt.

Iodoacetate. Sodium iodoacetate is an effective antiglycolytic agent (with the same caveats mentioned earlier) and a substitute for NaF. It inhibits creatine kinase but appears to have no notable effects on other clinical tests.

Influence of Site of Collection on Blood Composition

Blood obtained from different sites differs in composition. In general, skin puncture blood is more similar to arterial blood than to venous blood, depending on the collection condition as described earlier. Thus there are no clinically significant differences between freely flowing capillary blood and arterial blood in pH, PCO_2 , PO_2 , and oxygen saturation. The PCO_2 of venous blood is up to 6 to 7 mm Hg (0.8 to 0.9 kPa) higher. Venous blood glucose is as much as 70 mg/L (0.39 mmol/L) less than capillary blood glucose.

Collection of Blood From Intravenous or Arterial Lines

When blood is collected from a central venous catheter or arterial line, it is necessary to ensure that the composition of the specimen is not affected by the fluid that is infused into the patient. With clinical approval, fluid may be shut off using the stopcock on the catheter, and 10 mL of blood is aspirated through the stopcock and discarded before the specimen is withdrawn. In pediatric patients, 10 mL of blood is often not feasible, so less volume is aspirated, although the goal is still to aspirate approximately 3 times the dead space of the line before collecting the sample for testing. Aspirating this blood

and clearing the lines is equally important for molecular diagnostics and coagulation testing because the stopcock is often heavily saturated with heparin. Collection of samples for therapeutic drug monitoring should not be done from the line used for the infusion, irrespective of the time since infusion or amount of blood aspirated, because the drug may adhere to the line and leak into the collected sample.

In theory, blood may be collected from the veins of an arm below an IV line without interference from the fluid being infused because retrograde blood flow does not occur in the veins and the fluid that is infused must first circulate through the heart and return to the tissue before it reaches the sampling site. However, collection from the arm without the IV line is strongly recommended.

Hemolysis

Hemolysis is defined as the disruption of the RBC membrane, resulting in the release of hemoglobin, and may be the consequence of intravascular events (in vivo hemolysis) or may occur subsequent to or during blood collection (in vitro hemolysis). Serum and plasma show visual evidence of hemolysis when the hemoglobin concentration exceeds 50 mg/dL (7.7 $\mu\text{mol/L}$). Slight hemolysis has little effect on most but not all test values. Test interference at this concentration may be observed on those constituents that are present at a higher concentration in erythrocytes than in plasma, such as activities or concentrations of LDH, aspartate transaminase (AST), potassium, magnesium, and phosphate. Most manufacturers provide data on the effects of hemolysis on the analytical performance of individual tests, and this should be evaluated in the selection of individual methods. Laboratory personnel must define at what level of hemolysis results should be held and not reported to prevent poor clinical action on unreliable test results.

In molecular diagnostic testing, hemoglobin may interfere with the amplification reaction. In some situations the isolation of nucleic acid is sufficiently selective that free hemoglobin from the ruptured cells is removed and will not cause a problem. However, with hemolyzed blood, alternative or additional extraction methods are usually needed to ensure that RNA is fully and accurately transcribed and that the greatest amplification of DNA is achieved.

Urine

The timing of urine specimen collection is dictated by the tests to be performed. Untimed or random specimens are suitable for some chemical tests; usually, urine specimens must be collected over a predetermined interval of time, such as 4, 12, or 24 hours. A clean, early morning, fasting specimen is usually the most concentrated specimen and thus is preferred for microscopic examinations and for the detection of abnormal amounts of constituents, such as proteins, or of unusual compounds, such as chorionic gonadotropin. The clean timed specimen is one obtained at specific times of the day or during certain phases of the act of micturition. Although bacterial examination of the first 10 mL of urine voided is most appropriate to detect urethritis, the midstream

specimen is best for investigating bladder disorders. The double-voided specimen is the urine excreted during a timed period after complete emptying of the bladder; it is used, for example, to assess glucose excretion during a glucose tolerance test. Similarly, in some metabolic disorders, urine must be collected during or immediately after symptoms of the disease appear.

When they are to be tested for their alcohol and drugs of abuse content, urine specimens are collected under rigorous conditions, often including enhanced patient identification and special collection facilities where water that could be used for urine dilution is restricted or colored, for example. It is necessary for laboratory personnel to be aware of the relevant legal requirements for this type of testing and plan in advance how these samples and the supporting paperwork will be collected and handled.

Catheter specimens are used for microbiologic examination in critically ill patients and in those with urinary tract obstruction but should not normally be obtained just for examination of chemical constituents. The suprapubic tap specimen is a useful alternative because the tap is unlikely to cause infection. After appropriate cleaning of the skin over the full bladder, a 22-gauge spinal needle is passed through a small wheal made by a local anesthetic. The bladder is penetrated and the urine withdrawn into the syringe.

Even though tests in the clinical laboratory are not usually affected by lack of sterile collection procedures, the patient's genitalia should be cleaned before each voiding to minimize the transfer of surface bacteria to the urine.

Currently, urine is an uncommon specimen type in the molecular diagnostic laboratory for genomic testing, although some laboratories use urine samples for bladder cancer screening and monitoring of therapy for bladder cancer. However, urine is frequently used for molecular testing for infectious agents, such as *Chlamydia*, a common sexually transmitted organism, or BK virus, associated with potential rejection or failure of transplanted kidneys. Because most requests involve a specific organism, an untimed or random urine specimen collected into a sterile container with no preservative is usually acceptable.

Timed Urine Specimens

The collection period for timed specimens should be long enough to minimize the influence of short-term biologic variations. When specimens are to be collected over a specified period of time, the patient's close adherence to instructions to the collection procedure and restrictions to diet or drug ingestion is critically important and a common source of a preanalytical variable. The bladder must be emptied at the time the collection is to begin and this urine discarded. Thereafter all urine must be collected until the end of the scheduled time, including emptying of the bladder at the end of the collection period. Precautions should be taken to prevent fecal contamination of the urine. When the collection is made over several hours, urine should be passed into a separate container at each voiding and then emptied into a larger container for the complete specimen. This two-step procedure prevents the danger of patients

Fig. 6.3 Urine collection device used in children.

splashing themselves with a preservative, such as acid that may be included in the collection device. The large container generally should be stored at 4°C during the entire collection period.

Urine should not be collected at the same time for two or more tests requiring different preservatives. Removal of aliquots during the collection procedure is not permissible even when the volume removed is measured and corrected because excretion of most compounds varies throughout the day. Appropriate information regarding the collection, including warnings with respect to handling of the specimen, should appear on the container label.

When a timed collection is complete, the specimen should be delivered without delay to the clinical laboratory, where the volume should be measured by using graduated cylinders or by weighing the container and the urine when preweighed or uniform containers are used. The mass in grams may be reported as if it were the volume in milliliters.

Before a specimen is transferred into small containers for each of the ordered tests, it must be thoroughly mixed to ensure homogeneity because the specific gravity, volume, and composition of the urine all may vary throughout the collection period and settling may occur.

Collection of Urine From Children

Collection of any type of urine specimen from an infant is difficult, with timed collections being the most problematic. The approved method for collecting a random urine specimen from an infant involves a process known as bagging. A plastic bag (e.g., U-Bag, Hollister, Chicago, IL) is placed around the infant's genitalia after cleaning and then is held in place by a mild adhesive (Fig. 6.3). The baby's diaper is reapplied to help hold the bag in place. As soon as voiding has occurred, the bag containing the urine sample is removed and emptied into a regular urine collection cup. In infants, a random or spot urine collection for something as simple as a urinalysis may require either catheterization or a suprapubic tap collection. In infants and very young children requiring a rare 24-hour urine collection, hospitalization and catheterization are often required to obtain a complete collection.

Urine Preservatives

Preservatives for urine (CLSI GP16-A3, see Table 6.1) are usually added to reduce bacterial action or chemical decomposition or to solubilize constituents that otherwise might precipitate out of solution. Some specimens should not have any preservatives added because of the possibility of interference with analytical methods.

One of the most acceptable forms of preservation of urine specimens is refrigeration immediately after collection; it is even more successful when combined with chemical preservation. Acidification to a pH less than 3 is widely used to preserve 24-hour specimens for determination of calcium, steroids, adrenaline, noradrenaline, and vanillylmandelic acid. However, precipitation of urates will occur, making the sample unsuitable for measurement of uric acid.

A mild base, such as sodium bicarbonate or a small amount of sodium hydroxide, is used to preserve porphyrins, urobilinogen, and uric acid. pH should be adjusted to between 8 and 9.

Feces

Small aliquots of feces are frequently analyzed to detect the presence of "hidden" or occult blood. Guaiac-based occult blood screening is subject to many interferences causing both false-positive and false-negative results. Results should be interpreted cautiously unless the intent is to identify current bleeding in any portion of the gastrointestinal (GI) tract in an emergent patient. Newer immunochemical-based tests, so-called iFOB tests, have decreased the effects of food intake greatly for the purpose of identifying a lower GI tract bleed that may indicate the presence or possibility of malignant growth. However, iFOB methods will not detect upper GI bleeds. In either case, tests for occult blood should be done on aliquots of excreted stools rather than on material obtained on the glove of a physician doing a rectal examination because this procedure may cause enough bleeding to produce a positive result.

In newborns the first specimen from the bowel (meconium) may be used for detection of maternal drug use during the gestational period, which requires specific attention to the details of collection and identification similar to the chain of custody procedure for urine collection discussed earlier. Feces from infants and children may be screened for tryptic activity or for increased fecal fat concentrations, both of which can be indicators of cystic fibrosis. Fecal material is also commonly collected in childhood for the detection of parasites (ova and parasites [O & P]), enteric disease organisms such as *Salmonella* and *Shigella*, and viruses, all of which are useful in sorting out the differential diagnosis of diarrhea. Fecal testing is also used for helping to determine causes of malabsorption.

Usually, no preservative is added to the feces, but the container should be kept refrigerated throughout the collection period, and care should be taken to prevent contamination from urine. When the collection is complete, the container and feces are weighed, and the mass of excreted feces is calculated. Results are generally reported as activity per unit weight.

Other Body Fluids

Specimens may be collected for analysis from a range of different body fluids. These include cerebrospinal fluid (CSF), pleural fluid, ascitic fluid, pericardial fluid, amniotic fluid, synovial fluid, and others.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) allows for earlier (gestational period 10 to 12 weeks) diagnosis of inherited genetic disorders than is possible with amniotic fluid (gestational period 15 to 20 weeks) analysis. CVS is the technique of inserting a catheter or needle into the placenta and removing some of the chorionic villi, or vascular projections, from the chorion. This tissue has the same chromosomal and genetic makeup as the fetus and can be used to test for disorders that may be present in the fetus. After culture and growth for 3 weeks, DNA is extracted for analysis.

Buccal Cells

Collection of buccal cells (cells of the oral cavity of epithelial origin) has been identified as providing an excellent source of genomic DNA, as well as being less invasive than collection of blood. It is particularly useful for collecting cells with the patient's genomic DNA when the patient has had blood transfusions and thus another person's DNA or after bone marrow transplantation when the circulating blood cells are derived wholly or partially from the donor of the bone marrow. Two methods are used commonly to collect buccal cells: rinsing with mouthwash and using swabs or cytobrushes.

Rinsing of the oral cavity generally provides a higher yield of cells than can be obtained by using swabs. Mouthwash solutions high in phenol and ethanol are destructive to recovered cells and should be avoided. It is necessary for laboratory staff to validate a list of acceptable solutions.

For swabs, a sterile Dacron or rayon swab with a plastic shaft is preferred because calcium alginate swabs or swabs with wooden sticks may contain substances that inhibit PCR-based testing. After collection, the swab or cytobrush should be stored in an airtight plastic container or immersed in liquid, such as phosphate-buffered saline or viral transport medium.

Solid Tissue

Traditionally, the solid tissue most often analyzed in the clinical laboratory was malignant tissue from the breast for estrogen and progesterone receptors. Another traditional use is measurement of liver iron or copper to assist with the diagnosis of hemochromatosis or Wilson disease, respectively.

The same procedure may be used to obtain and prepare solid tissue for elemental or for toxicologic analysis; however, when trace element determinations are to be made, all materials used in the collection or handling of the tissue should be made of plastic or materials known to be free of contaminating trace elements.

Somatic gene analysis such as T and B cell clonality and the identification of possible clinically actionable mutations in malignant tissue (e.g., *KRAS* mutations) are now proving to be of increasing importance for clinicians in both diagnosis and direction of appropriate therapeutic options for the patient. For these studies, the molecular diagnostic laboratory often receives tissue that has been formalin fixed and paraffin embedded (FFPE) rather than fresh tissue because the request for further testing is generally made after the

pathologist's diagnosis of the particular malignancy. In general, neutral buffered formalin, containing no heavy metals, will not interfere with amplification reactions. DNA can still be extracted from tissue embedded in paraffin, but the DNA will be degraded to low-molecular-weight fragments. In most cases, segments of DNA will amplify in a PCR reaction, but Southern blot methods are problematic because most require high-molecular-weight DNA.

Hair and Nails

Currently, the use of hair or nails in molecular diagnostics is limited to forensic analysis (genomic DNA identification). Hair and fingernails or toenails have been used for trace metal and drug analyses, with the potential advantage of timing of exposure if separate segments of longer hair are analyzed, although no standards for such testing currently exist. Use of such samples requires laboratory staff to validate the processes.

HANDLING OF SPECIMENS FOR ANALYSIS

Steps that are important for obtaining a valid specimen for analysis include (1) identification, (2) preservation, (3) separation and storage, and (4) transport.

MAINTENANCE OF SPECIMEN IDENTIFICATION

Although the collection of an acceptable specimen is a key aspect of excellent testing, proper identification of the specimen must be maintained at each step of the testing process to ensure that the correct result is reported for the correct patient at all times. The minimum information on any label associated with a specific specimen should include the patient's name, location, and identifying number, as well as the date and time of collection. All labels should conform to the laboratory's stated requirements. In the United States, there is no specific labeling used for samples from patients with infectious diseases. Universal precautions should always be used, meaning that all specimens should be treated as if they are potentially infectious with the following caveat. The exception will be samples from patients suspected to have known, high-risk pathogens (e.g., hemorrhagic viruses such as Ebola) that must have separate, pre-prepared sample handling protocols that may or may not involve the routine laboratory. Proactive procedures must be in place, including by whom and where such samples might be analyzed, unless the sample can be rendered safe (e.g., by heat treatment), in which case again standard universal precautions should be used.

In practice, every specimen container must be adequately labeled, even if the specimen must be placed in ice or if the container is so small that a label cannot be placed along the tube, as might happen with a capillary blood tube. Direct labeling of a capillary blood tube by folding the label like a flag around the tube is recommended. For any specimen submitted in a screw-cap test tube or cup, the label should be placed on the cup or tube directly, not just on the cap.

It is critical that samples be positively identified through all steps of processing and analysis. Aliquoting a sample from the primary collection container to one or more other containers configured for the instrumentation requires close attention to proper labeling and tracking of the sample identifiers to ensure samples are not switched. Good work practice includes “piece work” in which only a single patient’s samples are in the work area at one time, the area is clean with no old labels present, and the worker is not disturbed. Because the majority of samples received from pediatric patients are in microtubes, most samples need to be aliquoted, poured into a microsampling device, or hand loaded onto instruments that use whole blood, because these systems are not made to deal with such small tubes. This extra handling of the specimens offers more opportunities for error and thus requires more strict attention to detail and analysis of the possible risks during design of the process.

Preservation of Specimens

Specimens must be properly treated both during transport to the laboratory and from the time the serum, plasma, or cells have been separated until analysis. For some tests, specimens must be kept at 4°C from the time the blood is drawn until the specimens are analyzed or until the serum or plasma is separated from the cells to minimize metabolism and degradation of sample components. Transfer of these specimens to the laboratory must be done by placing the specimen container on ice; a bag of ice is used to surround the sample to keep it cool while the sample and label are not subjected to possible water contamination.

For all test constituents that are thermally labile, serum and plasma should be separated from cells in a refrigerated centrifuge. Some specimens may need to be protected from both daylight and fluorescent light to prevent photodegradation, although the use of plastic, rather than glass, tubes has decreased this preanalytical variable.

For specimens that are collected in a remote facility with infrequent transportation by courier to a central laboratory, proper specimen processing must be done in the remote facility so that appropriately separated and preserved plasma or serum is delivered to the laboratory.

Add-on Requests

In the interest of preventing additional phlebotomies and to assess a clinical situation from a specimen collected at a specific time, many physicians request an “add-on” test (i.e., for the laboratory staff to perform a test on a sample already in the laboratory and processed). This is especially true in specimens collected from pediatric patients and for patients from an emergency department, where additional testing from the time of presentation with specific symptoms may be needed after a clinical diagnosis has been made or narrowed by the clinician. Each laboratory staff must establish its own guidelines for what will be allowed in what time frame.

Separation and Storage of Specimens

Plasma or serum should be separated from cells as soon as possible and certainly within 2 hours for some but not all analytes. However, premature separation of serum may permit continued formation of fibrin, which can clog sampling

devices in testing equipment. If it is impossible to centrifuge a blood specimen within 2 hours, the specimen should be held at room temperature rather than at 4°C to decrease any effect on potassium measurement caused by leakage from the RBCs by inhibition of the Na⁺,K⁺-ATPase pump. For most plasma samples used for molecular diagnostics, the plasma should be removed from the primary tube promptly after centrifugation and held at –20°C. In all instances of freezing a sample, frost-free freezers should be avoided because they have a wide temperature swing during the freeze-thaw cycle.

Primary specimen tubes should always be centrifuged with the original cap in place. Such containment reduces evaporation, which occurs rapidly in a warm centrifuge with the air currents set up by centrifugation. Caps on the original tube also prevent aerosolization of infectious particles. Specimen tubes with requested testing for volatiles, such as ethanol, *must* have the initial cap in place while they are spun to prevent release of the volatile compound and result in an artificially reduced measurement. Centrifuging specimens with the cap in place also maintains anaerobic conditions, which are important in the measurement of carbon dioxide and ionized calcium.

Transport of Specimens

Hemolysis may occur in pneumatic tube systems unless the tubes are completely filled and movement of the blood tubes inside the specimen carrier is prevented. The pneumatic tube system should be designed to eliminate sharp curves and sudden stops of specimen carriers. However, with many systems, the plasma hemoglobin concentration may be increased, and the serum activity of RBC enzymes, such as LDH and AST, may also be increased. There are also tests that cannot be transported to the laboratory via a pneumatic tube system such as platelet function testing where samples must be hand delivered to the laboratory.

Although the remaining discussion uses the specific example of referral laboratory testing, many of the issues discussed, such as regulations related to shipping, are also relevant to a laboratory that receives specimens from outlying clinics. This may involve validating specific transport or storage conditions that are in conflict with existing CLSI recommendations. Before a referral laboratory is used for any tests, the quality of its work should be verified by the referring laboratory. Guidelines for selection and evaluation of a referral laboratory have been published (GP 9-A, see [Table 6.1](#)). For laboratories accredited by the College of American Pathologists (CAP), it is a requirement that the referring laboratory validate that the referral laboratory is CLIA’88 certified by obtaining a copy of the Clinical Laboratory Improvement Act (CLIA) certificate before specimens are shipped. For molecular diagnostic testing, this is of particular importance because often the latest genetic test being requested by a physician has not yet been moved from research interest status to patient care status and may not be available in a CLIA-certified laboratory.

Specimen type and quantity and specimen handling requirements of the referral laboratory must be observed, and in laboratories operating under CLIA’88 regulations, test results reported by a referral laboratory must be identified as

such when they are filed in a patient's medical record. Most reference laboratories have lower minimum volume requirements for pediatric specimens than for adult specimens, but these lower minimums may preclude being able to retest the sample if there is a problem with the initial analysis. The tube and transport condition for the specimen should be constructed such that the contents do not escape if the container is exposed to extremes of heat, cold, or sunlight. Reduced pressure may be encountered during air transport, together with vibration, and specimens should be protected from these adverse conditions by a suitable container. Variability in temperature is a significant factor causing instability of test constituents.

Polypropylene and polyethylene containers are usually suitable for specimen transport. Containers must be leak-proof and should have a Teflon-lined screw cap that does not loosen under the variety of temperatures to which the container may be exposed. The materials of both stopper and container must be inert and must not have any effect on the concentration of the analyte.

For transport of frozen or refrigerated specimens, a Styrofoam container should be used. The container should be vented to prevent buildup of carbon dioxide under pressure and a possible explosion. Solid carbon dioxide (dry ice) is the most convenient refrigerant material for keeping specimens frozen. The amount of dry ice required in a container depends on the size of the container, the efficiency of its insulation, and the length of time for which the specimens must be kept frozen.

Various laws and regulations apply to the shipment of biologic specimens. Although such regulations theoretically apply only to etiologic agents (known infectious agents), all specimens should be transported as if the same regulations apply. Airlines deem dry ice a hazardous material; therefore

the transport of most clinical laboratory specimens is affected and those who package the specimens should be trained in the appropriate regulations, such as those published by the International Air Transport Association.

The various modes of transport of specimens influence the shipping time and cost, and each laboratory staff needs to make its own assessment as to adequate service. The objective is to ensure that the properly collected, processed, and identified specimen arrives at the testing facility in time and under the correct storage conditions so that the analytical phase can proceed.

CONCLUSION

Accurate test results (always the right result for the right patient) begin and end with the integrity of the sample being tested. Integrity can be assured only by proper preparation of the patient; choice of sample container; collection of the sample; and finally transport, processing, and storage of the collected sample, with each step maintaining accurate identification. For these reasons, best laboratory practice demands attention to detail and following appropriate protocols. It is incumbent on laboratory professionals to fully delineate their processes in complete policies and procedures that not only cover the routine and correct procedures but also cover the unusual. These should include how to handle the process when the system breaks down and steps are not properly performed and may need to be addressed case by case by the laboratory director. Finally, laboratory staff should fully validate protocols that may not be covered under normal procedures or that may deviate from local regulatory guidelines (e.g., the US Food and Drug Administration or CLIA). Preanalytical variables can be lessened or even avoided if these steps are followed.

POINTS TO REMEMBER

- Proper identification of the patient is essential; samples should be properly labeled at all steps if separated from the primary collection container.
- Collection of all samples must be in the correct primary container and never transferred to another primary container.
- Attention to the details related to processing of the collected sample (time, temperature, special handling) should always follow validated policies.
- The accurate result for any patient's sample (that will be acted on by the clinician) depends on adherence to all policies and procedures.

REVIEW QUESTIONS

1. Identify the incorrect specimen collection scenario below.
 - a. Ask a parent to name a pediatric patient.
 - b. Ask an adult patient to state his or her name and another identifier.
 - c. Show the patient or parent the labeled tube after collection is complete.
 - d. Check the room and bed number of the patient to be collected and proceed with collection.
 - e. Contact a translation service for a patient unable to speak the local language.
2. Identify the correct tube (additive)/biochemical action below:
 - a. Lavender (EDTA)/anticoagulated specimen that will limit effects on cell morphology
 - b. Light blue (ACD)/chelation of calcium to allow effective coagulation testing
 - c. Red (no additive, no gel)/serum sample that can be sampled directly by many analyzers
 - d. Light green/no gel/sodium–heparin tube prevents any further cellular activity that might affect analytes such as glucose
 - e. Dark green/lithium heparin/requires prompt removal of the plasma from the cell pellet

3. Patients should not pump their fists after the tourniquet is applied because
 - a. it may or may not cause venous stasis not under the control of the collector.
 - b. it will affect the chemical interaction between the tube additive and the patient's blood.
 - c. metabolic activity of the blood and muscles will affect analytes such as potassium and calcium through effects on pH.
 - d. it will affect the distribution of analytes between plasma and serum.
 - e. it will make it more difficult to find the patient's vein.
4. For urine collections, which of the following is true?
 - a. Samples should be kept at room temperature for a timed collection.
 - b. Special identification of the patient may be required for forensic purposes.
 - c. Identification of added preservative does not need to be communicated to the patient because all are safe.
 - d. For a 24-hour collection, the patient may collect into a rinsed milk jug and then pour the sample into the provided container at the end of the collection period.
 - e. No special handling is required because of collection preservative if the sample is sent to another laboratory.
5. Additional testing requested by the clinician treating the patient (add-on testing) should always be carried out, when
 - a. the sample was not stored correctly per local validated storage policies.
 - b. the patient is not identified correctly.
 - c. the request is for a labile compound that may have been affected by storage
 - d. the sample needs to be retrieved from a waste container.
 - e. the request is for a test that has been validated on the sample submitted.

Quality Management

W. Greg Miller, Sverre Sandberg*

OBJECTIVES

1. Define the following:
 - Coefficient of variation
 - External quality control
 - Internal quality control
 - Levey-Jennings chart
 - Mean
 - Proficiency testing
 - Quality control plan
 - Quality control rules
 - Sigma metric
 - Standard deviation (SD)
 - SD interval
2. Explain how to establish a target value and SD for use with a quality control material in the following situations: a new lot of quality control material replaces an existing lot for an analyte; a new measurement procedure replaces an existing procedure for the same analyte; a new measurement procedure for a new analyte is introduced to the laboratory.
3. Explain how to establish rules for evaluating quality control sample results to confirm that results for patient samples from a measurement procedure are acceptable to make medical decisions.
4. Explain how to verify quality control (QC) target values following a reagent lot change.
5. Explain the components of a quality control plan and how the plan is established.
6. Explain the actions taken when a failed quality control result is obtained.
7. Explain how to evaluate results from external quality assessment (EQA) or proficiency testing.
8. Explain why peer group evaluation is used in EQA and what information a laboratory gets about its measurement procedure performance from the data.
9. Explain the limitations in using peer group mean values to assess the relationship of results among different measurement procedures.
10. Explain the value of EQA that uses commutable samples.
11. Explain how quality control information is documented and reviewed by laboratory staff.

KEY WORDS AND DEFINITIONS

Coefficient of variation Also called *relative standard deviation*; calculated as the standard deviation (SD) divided by the mean and multiplied by 100 to express in percent.

External quality assessment Also called *external quality control* or *proficiency testing*; an assessment process in which samples that simulate patient specimens are received from an external organization and results compared to those from other laboratories or from a reference method to determine that a measurement procedure's performance meets preestablished criteria to be suitable for use in medical decisions.

Internal quality control Term used to refer to quality control as defined here to confirm that results from a measurement procedure are suitable for use.

Levey-Jennings chart A graphical display with observed control values plotted on the y-axis and time (typically in days) shown on the x-axis. The y-axis shows the target value with plus and minus 1, 2, and 3 SDs indicated. Control limits can be indicated but are not practical to show on the chart when multiple control rules are used for evaluation of quality control results.

Mean The arithmetic average of a series of numbers such as results of repeated measurements of a quality control sample. The mean of a series of replicate results for a quality control material is used as the target value for future measurements of that quality control material.

Proficiency testing Another term for external quality assessment.

*Some of this material was previously published in McPherson, R. A., & Pincus, M. R. (Eds.), (2016). *Henry's clinical diagnosis and management by laboratory methods* (23rd ed.). St. Louis: Elsevier.

Quality assessment Protocols to confirm that the laboratory service meets the needs of medical providers who use laboratory results for medical decisions. Quality assessment includes preanalytical, analytical, and postanalytical components of quality.

Quality control Statistical and/or nonstatistical check protocols, typically using quality control samples that are surrogates for the patient samples being tested, to assess that results from a measurement procedure meet preestablished criteria to be suitable for use in medical decisions.

Quality control plan A document that describes the organization and operation of the internal quality control process.

Quality control rules A set of rules that results for one or more quality control samples must meet to make a decision that the measurement procedure performance is

producing results for patient samples that are suitable for use in medical decisions.

Sigma metric A value that expresses the variation in performance of a measurement procedure relative to the allowable variability in results to be suitable for medical decisions expressed in SD units. Six-sigma performance means that six SDs of measurement procedure variation fit within the allowable limits for acceptable performance.

Standard deviation A statistical value that estimates the dispersion of replicate values around a mean value. A SD assumes a Gaussian distribution of values that is typically observed for numeric quality control results.

Standard deviation interval The number of SDs an individual result is from a mean value calculated as mean minus individual value divided by SD. The SD interval can be positive or negative relative to the mean value.

The purpose of a clinical laboratory test is to provide information on the pathophysiological condition of an individual patient to assist with diagnosis, therapy, or to assess risk for a disease. **Internal quality control**, frequently referred to as **quality control** (QC), is a statistical sampling approach performed by a laboratory on a regular schedule to assess performance of its measuring systems. External QC, frequently referred to as **external quality assessment** (EQA) or **proficiency testing** (PT) is an approach to assess measuring system performance by comparison of results for samples measured by a group of different laboratories. Both types of QC are addressed in this chapter (see later section for EQA/PT).

Internal QC evaluates a measurement procedure by periodically measuring a QC sample for which the expected result is known in advance. If the result for a QC sample is within acceptable limits of the known value, the measurement procedure is verified to be performing as expected, and results for patient samples can be reported with high probability that they are suitable for clinical use. If a QC result is not within acceptable limits, the measurement procedure is not performing correctly, there is a high probability that results for patient samples are not suitable for clinical use, and corrective action is necessary. Patient sample measurements could need to be repeated when the measurement procedure has been restored to its stable performance condition. If erroneous results have already been reported before an error condition is identified, a corrected report must be issued.

Measurement procedures fall into one of two general categories from a **QC plan** perspective. One type of procedure is a “batch” measurement process in which the results for patient samples and QC samples are completed before the results are reported. The other type of procedure is a “continuous” measurement process in which patient sample results are reported during the interval between QC samples measurements. For continuous measurement procedures, there is a possibility that erroneous results have already been reported if an error condition is identified by the next QC samples measurements. In either category, QC procedures only identify error

conditions present at the point in time when a QC sample is measured.

The design of a QC plan must consider the analytical performance capability of a measurement procedure and the risk of harm to a patient that might occur if an erroneous laboratory test result is used for a clinical care decision.

POINTS TO REMEMBER

Internal Quality Control

- The primary role of internal QC is to confirm that patient results are correct and to identify possible errors before they will affect patient care decisions.

MEASUREMENT PROCEDURE PERFORMANCE AS A PREREQUISITE FOR A QUALITY CONTROL PLAN

Analytical Bias and Imprecision

Fig. 7.1 illustrates the meaning of bias and imprecision for a measurement procedure. The horizontal axis represents the numeric value for an individual result, and the vertical axis represents the number of repeated measurements with the same value made on samples of a QC material. The *blue line* shows the dispersion of results for repeated measurements of the same QC material, which is the random imprecision of the measurement. The **standard deviation** (SD) is a measure of expected imprecision in a measurement procedure when it is performing within specifications. The **mean** of repeated measurements of a QC sample becomes the expected value for that QC sample.

Fig. 7.1B illustrates that if a systematic bias (error) occurs in the measurements, the mean value shifts to another value. Note that the imprecision is the same as before the bias occurred because it is unlikely, although not impossible, that a change in imprecision would occur at the same time as a bias shift. The primary purpose of measuring QC samples is to statistically evaluate the measurement procedure to

Fig. 7.1 (A) Distribution of results showing the mean value and expected imprecision for repeated measurements of a quality control sample. (B) Bias when a change in calibration has occurred. *SD*, Standard deviation. (From Miller, W. G. [2016]. *Quality control*. In: *Henry's clinical diagnosis and management by laboratory methods* [23rd ed.]. Philadelphia: Elsevier.)

verify that it continues to perform within the specifications consistent with its acceptable expected stable condition or to identify that a change in performance occurred that needs to be corrected. QC result acceptance criteria are based on the probability for an individual QC result to be different from the variability in results expected when the measurement procedure is performing in a stable condition within its specifications.

Fig. 7.2 shows a **Levey-Jennings chart** that is the most common presentation for evaluating QC results. This format shows each QC result sequentially over time and allows a quick visual assessment of performance. Assuming the measurement procedure is performing in a stable condition, the mean value represents the target (or expected) value for the QC result, and the SD lines represent the expected imprecision. Assuming a Gaussian (normal) distribution of imprecision, the results should be distributed uniformly around the mean with results observed more frequently closer to the mean than near the extremes of the distribution. The data show fluctuations in performance at different intervals and illustrate the importance of calculating the SD over a long enough interval to appropriately include all sources of variability in the measurement procedure. Note that a small number of results in Fig. 7.2 are greater than 2 SDs, and three results slightly exceed 3 SDs, which is expected for an approximately Gaussian distribution of imprecision. The number of results expected within the **standard deviation intervals** (SDIs) is:

- ± 1 SD = 68.3% of observations
- ± 2 SD = 95.4% of observations
- ± 3 SD = 99.7% of observations

Interpretation of an individual QC result is based on its probability to be part of the expected distribution of results

Fig. 7.2 Levey-Jennings chart of quality control (QC) results ($n = 1232$) for a single lot of QC material used over a 10-month period. *SD*, Standard deviation. (Reprinted with permission from Miller, W. G., & Nichols, J. H. [2011]. *Quality control*. In: W. A. Clarke [Ed.], *Contemporary practice in clinical chemistry* [2nd ed.]. Washington, DC: AACC Press.)

for the measurement procedure when the procedure is performing correctly. Note that evaluation of individual QC results may be performed by computer algorithms without visual examination of a Levey-Jennings chart.

Performance of a Measurement Procedure for Its Intended Medical Use

It is necessary to determine how the performance of a measurement procedure relates to the medical requirements for interpreting results to determine the frequency to measure QC samples and the criteria to use to evaluate the QC results. The **sigma metric** is commonly used to assess how well a measurement procedure performs relative to the medical requirement. For laboratory measurements, the sigma metric is calculated as:

$$\text{Sigma} = \frac{(\text{TE}_a - |\text{bias}|)}{\text{SD}}$$

where TE_a is the total error allowed based on medical requirements, and absolute value of bias and SD refer to performance characteristics of the measurement procedure. The SD is estimated from the QC data. It is critically important that the estimate of SD be made using QC data that represent all or most components of variability that occur over an extended time period. The bias is difficult for a laboratory to estimate because it is difficult to evaluate if a particular measurement procedure has a bias compared with a reliable estimate of a true value such as a reference measurement procedure. For internal QC, a laboratory is usually interested to determine if a bias has occurred compared with the condition established by calibration of a measurement procedure, and if a bias has occurred it will be corrected. Consequently, the bias is usually assumed to be zero for calculating sigma.

TE_a represents the measurement procedure performance required for medical decisions based on a test result. TE_a can be estimated using three models. The preferred model (model 1) is to set a performance specification based on an outcome study such as the impact of analytical performance on the clinical outcome. Outcome studies are only available for a small number of analytes and typically included in clinical laboratory practice guidelines.

Model 2 bases the TE_a on a fraction of the within and between individual biological variations of the measurand. (For additional information on biological variation refer to [Chapter 4](#).) This model minimizes the ratio of the “analytical noise” to the “biologic signal,” with an assumption that a small ratio will identify measurement procedure performance that relates to the medical requirements. Tables of optimal, desirable, and minimal TE_a based on biological variation are available.

Model 3 bases the performance specifications on the “state of the art,” which is the performance capability of a measurement procedure usually derived from QC data. The laboratory should consult with clinical care providers to agree on an appropriate TE_a for the patient population served.

Because sigma assumes a Gaussian or normal distribution for repeated measurements, the probability of a defect (i.e., an erroneous laboratory result) can be predicted. The term *six-sigma* refers to a condition when the variability in the measurement process is sufficiently smaller than the medical requirement that erroneous results are very uncommon. [Fig. 7.3A](#) shows a six-sigma test that has the TE_a limits 6 SDs away from the center point of the distribution of variability in measurements. A small amount of bias or increased imprecision will have little influence on the number of erroneous results produced, and the risk of producing an erroneous result even with some loss of performance is very low. Consequently, less stringent QC is suitable.

[Fig. 7.3B](#) shows a three-sigma measurement procedure that has the TE_a limits 3 SDs away from the center point of the expected distribution of variability in measurements. In the three-sigma situation, a small amount of bias or increased imprecision will cause the number of erroneous results to increase substantially. More frequent QC and more stringent acceptance criteria will allow the laboratory to identify when small changes in performance occur so they can be corrected to minimize the risk of harm to a patient from erroneous results being acted on to make clinical care decisions.

Fig. 7.3 Test performance relative to the sigma scale to describe how well performance meets medical requirements expressed as the allowable total error (TE_a). (A) A six-sigma measurement procedure. (B) A three-sigma measurement procedure. (From Miller, W. G. [2016]. *Quality control*. In: *Henry's clinical diagnosis and management by laboratory methods* [23rd ed.]. Philadelphia: Elsevier.)

POINTS TO REMEMBER

- The performance characteristics of a measurement procedure when it is performing in a stable in-control condition must be known.
- The allowable total error for a measurement procedure must be established based on requirements for using a laboratory result in patient care decisions.
- The sigma metric represents the probability that a given number of erroneous results may occur when the test measurement procedure is performing to its specifications.

DEVELOPING A QUALITY CONTROL PLAN AND IMPLEMENTING INTERNAL QUALITY CONTROL PROCEDURES

Selection of Quality Control Materials

In general, two different concentrations of QC materials are necessary for adequate statistical QC. For quantitative measurement procedures, QC materials should be selected to provide analyte concentrations that represent clinical decision values over the analytical measuring interval of the measurement procedure. More than two concentrations of QC materials may be needed when there are several important medical decision values. In practice, laboratories are frequently limited by concentrations available in commercial QC products. For procedures with extraction or other pretreatment steps, controls must be used to include any pretreatment steps. For qualitative tests, QC values should assess the stability of a threshold for a classification decision.

The QC materials must be manufactured to provide a stable product that can be used for an extended time period when possible. Use of a single lot for a year or more allows reliable interpretive criteria to be established that will minimize the effort and uncertainty associated with QC lot changes.

Limitations of Quality Control Materials

An important limitation of most QC materials, which also applies to EQA or PT materials, is called noncommutability

with patient samples. Fig. 7.4A shows that a commutable QC material gives a result that closely agrees with results for authentic patient samples with the same amount of analyte when measured by different procedures. Fig. 7.4B shows that results for a noncommutable QC material have a different relationship than observed for patient samples when measured by different procedures. QC and EQA/PT materials are typically noncommutable with patient samples because the serum or other biologic fluid matrix is usually altered from that of a patient sample during product manufacturing, for example, by use of partially purified human and nonhuman additives to achieve desired concentrations and various stabilization additives and processes. The impact of the matrix alteration on the recovery of a measurand is not predictable and is frequently different for different lots of QC material, for different lots of reagent within a given measurement procedure, and for different measurement procedures. Because of the noncommutability limitation, special procedures are required when changing lots of reagent or comparing QC results among two or more measurement procedures.

A second limitation of QC materials is gradual deterioration of the analyte during storage and after reconstitution, thawing, or vial opening.

Frequency to Measure Quality Control Samples

The frequency to measure QC samples depends on several considerations. Regulatory requirements may specify a minimum frequency for QC measurements. The instructions for use from measurement procedure manufacturers may specify a minimum or recommended QC frequency. The risk of action being taken before a measurement error of clinical importance is detected is an important consideration for more frequent QC measurements than based on regulatory requirements or manufacturer's recommendations.

Analytical Stability of the Measurement Procedure

The more stable the measurement procedure, the less frequently a QC evaluation needs to be performed. Some

Fig. 7.4 Illustration of commutable and noncommutable materials. (A) Commutable materials (blue squares) have the same relationship between two measurement procedures as observed for patient samples (black diamonds). (B) Noncommutable materials have a different relationship than observed for patient samples. EQA, External quality assessment; PT, proficiency testing; QC, quality control.

measurement procedures, particularly point-of-care (POC) devices, have been designed with sophisticated built-in control procedures to mitigate the risk that an erroneous result may be produced. These measurement systems may be sufficiently stable and self-monitored to justify reduced frequency of traditional QC sample testing.

Risk of Harm to a Patient and Number of Patients Who May be at Risk

More frequent QC sampling is appropriate to avoid the situation of discovering a measurement procedure defect many hours after a physician has made a clinical treatment or non-treatment decision based on an erroneous result. For example, QC sampling performed on a 24-hour cycle might be performed at 9 a.m. If QC results indicate a measurement procedure problem, the erroneous condition could have started at any time during the previous 24 hours. If the problem had occurred at 3 p.m. the previous day, erroneous results could have been reported for 18 hours, likely putting a large number of patients at risk of an inappropriate care decision.

The Clinical and Laboratory Standards Institute (CLSI) has published guideline EP23 addressing risk-based QC procedures. The document provides guidance on how to develop a QC plan based on evaluation of risk of harm to a patient and assessment of the effectiveness of risk mitigation procedures. In general terms the laboratory director makes a judgment that suitable built-in and laboratory-applied controls are in place and that a result has a high probability to be correct at the time it is reported for clinical use.

Event-Based Quality Control Sample Measurement

It is necessary when using a continuous measurement system to measure QC samples before and after scheduled events such as recalibration or maintenance that may alter the current performance condition. Each of these operations is intended to restore the measurement conditions to optimal specifications and to correct for any calibration drift or component deterioration that may have occurred. If QC samples are not measured before such scheduled events, a laboratory will not know if an error condition may have occurred since the last time QC samples were measured. It is also necessary to measure QC samples after these events to verify that the operations were performed correctly and that measurement procedure performance meets specifications before restarting to measure patient samples.

Establishing the Quality Control Target Value and Standard Deviation That Represent a Stable Measurement Operating Condition

QC target values and acceptable performance limits are established to optimize the probability to detect a measurement defect that is large enough to have an impact on clinical care while minimizing the frequency of “false alerts” caused by statistical limitations of the criteria used to evaluate QC results.

Quality Control Material Target Value

The generally accepted minimum protocol for target value assignment is to use the mean from a minimum of 10

measurements of the QC material on 10 different days when the measurement procedure is correctly calibrated and performing to its specifications. Because all sources of variability cannot be captured in 10 measurements, it is recommended to update the target value after more data have been acquired during use of the QC material. If a 10-day protocol is not possible (e.g., if an emergency replacement of a lot of QC material is necessary), a provisional target value can be established with fewer data but should be updated when additional QC results are available.

Quality Control Material Standard Deviation

The SD must represent the variability expected for a measurement procedure over an extended time interval to include all sources of variability when its performance meets its specifications. Measurement variability has short time interval components (such as pipetting volume), gradual changes (such as pipet seal deterioration or coating of cuvette or electrode surfaces), or variable and sometimes long intervals (such as calibration cycles, reagent replenishment, and maintenance procedures). An SD that represents stable measurement performance can usually be estimated from the cumulative SD over a 6- to 12-month period for a single lot of QC material because most expected sources of variation are likely to be represented. Fig. 7.5 illustrates the fluctuation in SD that occurred when calculated for monthly intervals compared with the relatively stable value observed for the cumulative SD after a period of 6 months. Note that the cumulative SD is not the average of the monthly values but is the SD determined from all individual results obtained over a time interval since the lot of QC material was first used. If the imprecision expected during normal stable operation is underestimated, the acceptable range for QC results will be too small, and the false-alert rate will be unacceptably high.

When a measurement procedure has been established in a laboratory and a new lot of QC material is being introduced,

Fig. 7.5 Cumulative standard deviation (SD) versus single monthly values calculated from the data in Fig. 7.2. (From Miller, W. G. [2016]. *Quality control*. In: *Henry's clinical diagnosis and management by laboratory methods* [23rd ed.]. Philadelphia: Elsevier.)

TABLE 7.1 Abbreviation Nomenclature for Quality Control Evaluation Rules

Rule	Meaning	Detects
1 _{2S}	One observation exceeds 2 SDs from the target value. The 1 _{2S} rule is not recommended except for low sigma measurement procedures because it has a high false-alert rate.	Bias or imprecision
1 _{3S}	One observation exceeds 3 SDs from the target value.	Bias or large imprecision
2 _{2S} (2 _{2.5S})	Two sequential observations, or observations for two QC samples measured at approximately the same time, exceed 2 SDs (or 2.5 SDs) from the target value in the same direction.	Bias
2 of 3 _{2S}	Two observations for three QC samples measured at approximately the same time exceed 2 SDs from the target value in the same direction. Note that this type of rule is used when three QC materials are used for a measurement procedure.	Bias
R _{4S}	Range between observations for two QC samples measured at approximately the same time, or for two sequential observations of the same QC sample, exceeds 4 SDs.	Imprecision
10 _x or 10 _m	Ten sequential observations for the same QC sample are on the same side of the target value (x or mean). The 10 _x rule is not recommended because it has an excessive false-alert rate.	Not recommended
8 _{1S} (8 _{1.5S})	Eight sequential observations for the same QC sample exceed 1 SD (or 1.5 SD) in the same direction from the target value.	Bias trend
CUSUM	CUSUM of SDI for the current and previous results.	Bias trend
EWMA	EWMA for the current and previous results with newer results having more influence (weight).	Bias trend

CUSUM, Cumulative sum; EWMA, exponentially weighted moving averages; QC, quality control; SD, standard deviation; SDI, standard deviation interval.

From Miller, W. G. (2016). Quality control. In: *Henry's clinical diagnosis and management by laboratory methods* (23rd ed.). Philadelphia: Elsevier.

the target value for the new lot of QC material is used along with the well-established SD from the previous lot. This practice is appropriate because in most cases, measurement imprecision is a property of the measurement procedure and equipment used and is unlikely to change with a different lot of QC material.

When a new measurement procedure replaces an existing procedure, the SD for the existing procedure can in many cases be used as the initial SD for the new measurement procedure until the SD for the new measurement procedure has been established. An assumption is made that the SD for the existing measurement procedure was appropriate to ensure the results were suitable for use in medical decisions, consequently that SD is likely to be suitable for QC decisions for the new measurement procedure.

If a measurement procedure for a new analyte is introduced, there will not be any historical performance information. The SD is based on QC data obtained during the measurement procedure validation. A minimum of 20 observations on different days is recommended for the initial estimate of the SD. This initial estimate of SD will likely be an underestimate because it does not include all sources of variability and must be updated when sufficient QC results have been accumulated to include most sources of variability.

Quality Control Materials With Preassigned Values

Some QC materials are provided by the measurement procedure manufacturer with preassigned target values and acceptable ranges intended to confirm that the measurement procedure meets the manufacturer's specifications. Such assigned values may be used to verify the manufacturer's specifications. However, it is recommended that both the target value and the SD should be reevaluated and assigned by the laboratory after adequate replicate results have been

obtained because the QC interpretive rules used in a single laboratory should reflect performance for the measurement procedure in that laboratory.

QC materials with assigned target values and SDs are also available from third-party manufacturers (i.e., manufacturers not affiliated with the measurement procedure manufacturer) and typically have values that are applicable to specifically stated measurement procedures and reagent lots to accommodate the influence of noncommutability. However, a laboratory should determine a target value and SD that reflect the operating conditions in that laboratory to ensure optimal assessment of QC results to identify an erroneous measurement condition.

Establishing Rules to Evaluate Quality Control Results

The acceptable range and rules for interpretation of QC results are based on the probability of detecting an analytical error condition with an acceptably small false-alert rate.

The conventional way to express QC interpretive rules is by using an abbreviation nomenclature popularized among clinical laboratories by Westgard and summarized in Table 7.1. Note that fractional SDIs can be used as in the 2_{2.5S} and 8_{1.5S} examples and that combinations of numbers of controls and limits can be used as appropriate for QC interpretive rules. Trend detection procedures such as cumulative sum (CUSUM) or exponentially weighted moving average (EWMA) are recommended if supported by an available computer system because they are more powerful for detecting trends than approaches based on counting the number of sequential observations exceeding a specified SDI. A trend rule can be set to give an alert as a warning that may not require discontinuing testing but indicate that a problem is developing that should be investigated.

TABLE 7.2 Empirical Multirule for the Quality Control Data Presented in Fig. 7.2

Multirule Components	Type of Variability Detected
1_{3S}	Imprecision or bias
$2_{2.5S}$	Bias
R_{4S}	Imprecision
$8_{1.5S}$	Bias trend

From Miller, W. G. (2016). Quality control. In: *Henry's clinical diagnosis and management by laboratory methods* (23rd ed.). Philadelphia: Elsevier.

It is recommended to improve the efficiency of QC interpretive rules by combining two or more rules and applying them simultaneously as multirule criteria. For example, the $1_{3S}/2_{2S}$ multirule identifies an error condition if one control exceeds ± 3 SD from the target value or if two controls exceed ± 2 SDs in the same direction from the target value. The $1_{3S}/2_{2S}$ multirule has a low false-alert rate but improved probability to detect a bias error of a given magnitude.

In practice, empirical judgment is frequently used to establish acceptance criteria (rules) to evaluate QC results based on data acquired over a long enough period of time to adequately estimate the expected variability when a measurement procedure is working correctly. An empirical approach can be used by obtaining a set of QC data that represents stable measurement procedure performance over a time interval expected to include most sources of variability. Using those data, the false-alert rate for a rule can be determined, and bias errors of different magnitudes can be added to estimate the ability of a rule, or a combination of rules, to identify that error. Table 7.2 gives an example of an empirically developed multirule for a 6-sigma measurement procedure. Such control rules should allow the laboratory to detect errors before they are of a magnitude that will affect clinical decisions. A 10_x rule was not used because it would have increased the false-alert rate by 10.6%. A 10_x rule or other rule that counts the number of sequential QC results on one side of the target value is not recommended because this condition typically does not indicate a problem with clinical interpretation of patient results when the magnitude of the difference from the target value is small. Counting the number of sequential results that exceed a larger SD from the target value, such as $8_{1.5S}$ in this example, is more likely to represent a measurement condition that might need investigation.

For measurement procedures with small sigma values, small deviations from the expected performance need to be identified. Consequently, more stringent QC practices need to be used such as selecting rules such as 1_{2S} that will give an alert at smaller error conditions, using additional rules in a multirule set, measuring QC more frequently, using more than two QC samples, and not releasing patient results until QC assessment is complete for the time interval during which patient samples were measured. More stringent QC rules will have more false alerts, but this is an unavoidable cost when lower sigma measurement procedures are used.

Specifying the Quality Control Plan

The preceding subsections describe the considerations for each component in a QC plan. The laboratory director is responsible for considering the components, making judgments regarding the considerations, and approving the final plan for each analyte measured in a laboratory. A plan for internal QC specifies the following components:

- The number of QC samples to be measured and the approximate concentrations of analytes in those controls
- The target value for each QC sample
- The SD for each QC sample to be used in the QC rules
- The rules for evaluating the QC results
- The frequency to test the QC samples

Considerations for Point-of-Care Testing

Internal QC of POC instruments offer extra challenges compared with those addressed at the central laboratory. The main reasons are that POC instruments are often operated by persons without laboratory training; they often use methodologic principles that are different from those in the central laboratory; they often have “built-in” controls; and the number of measurements can be small, making the use of QC samples in the traditional way expensive. In cartridge-based and some strip-based instruments, the manufacturer often has placed the technology in the cartridge or strip together with QCs, and in some cases, QC rules are built in so that patient results cannot be reported unless the QC is “satisfactory.” The instrument is then merely an electronic reader that often has incorporated an “electronic quality control” that verifies the electronics of the measurement procedure. The electronic instrument checks do not verify the reagents in the cartridges or strips, and unless each cartridge has internal QC materials, the reagent cartridges or strips should be checked at delivery and then at intervals (e.g., with the arrival of a new shipment or lot or at a suitable interval such as weekly or monthly depending on the cartridges/strips).

Not all POC instruments include enhanced QC features. In these cases, one must rely on daily liquid QC performed by the operator. The limitation of using the liquid QC sample in this situation is that it only checks if one disposable cartridge or strip meets the performance specifications. This limitation requires an assumption that all devices in a lot were manufactured uniformly and will perform equivalently.

How internal QC should be performed and supervised also depend on the location of the POC instruments. In a hospital, it is now possible with real-time bidirectional connectivity between the POC devices and the central laboratory to transfer both patient and QC results and to set lock-out parameters for conformance to a QC protocol. As technology advances, the general trend is for more sophisticated POC devices with built-in control systems to be incorporated to minimize or prevent the possibility for an incorrect result.

Corrective Action When a Quality Control Result Indicates a Measurement Problem

A QC alert occurs when a QC result fails an evaluation rule, which indicates that an analytical problem may exist. A QC

Fig. 7.6 Generalized troubleshooting sequence showing the initial steps after an unacceptable quality control (QC) result. The details of troubleshooting the defect may be different for different rules violations or if more than one unacceptable QC result was obtained.

alert means there is a high probability that the measurement procedure is producing results that have the potential to be unreliable for patient care and testing must be stopped until the problem is resolved. Fig. 7.6 presents a generalized troubleshooting sequence. QC materials can deteriorate after opening because of improper handling and storage or because of unstable analytes. Thus repeating the measurement on a new vial of the QC material is a useful step to determine if the alert was caused by deteriorated QC material rather than by a measurement procedure problem. In this situation, if the result for the new QC sample is acceptable, testing of patient samples can resume. One caution when the repeat QC result is near acceptability limits is to consider whether the

repeat and original results are essentially the same. It is not acceptable to repeat the QC until a value happens to be just within the acceptable limit. In this situation the probability is high that a measurement problem exists, and this possibility should be investigated. In addition, current and preceding QC results should be examined for a trend in bias that indicates a measurement issue that needs to be corrected. These precautions in evaluating repeat results for a new QC sample can be challenging or impossible for automated evaluation by computer systems, thus requiring the laboratory technologist to be vigilant in reviewing results.

When repeat testing of a new QC sample does not resolve the alert situation, the instrument and reagents should be

inspected for component deterioration, empty reagent containers, mechanical problems, and so on. In many cases, it will be necessary to recalibrate. When the problem is identified and corrected, QC samples should be measured to verify the correction, and all patient samples since the time of the last acceptable QC results, or the time when the error condition occurred, should be measured again. The laboratory director must establish acceptable criteria to determine if the repeat results agree adequately to permit reporting of original results without issuing a corrected report. Otherwise, corrected results must be reported. The criteria for acceptability of repeated tests are based mainly on the TE_a described earlier with consideration of the measurement procedure performance characteristics.

It may be difficult to establish the time when an error condition occurred. One approach is to repeat every few samples back to the time of the last acceptable QC results. The repeated results are then compared with acceptable criteria for repeated results agreement to identify a point in time when the error condition occurred. When selecting the samples to repeat, it is important to ensure that a substantial representation of the potentially erroneous samples is repeated and that samples at a concentration consistent with that of the unacceptable QC are represented. Alternatively, groups of 10 patient samples can be repeated, again ensuring that samples at a concentration consistent with that of the unacceptable QC are represented, until all repeat results in at least two sequential groups are within acceptable criteria for repeated results. When the point at which the error condition was likely to have occurred is identified, all patient samples must be repeated from that point until the unacceptable QC result was obtained. Any assessment of the point at which an error condition occurred by repeating selected patient samples has a risk to incorrectly identify that point, and laboratories are encouraged to repeat enough patient samples to have confidence in the assessment.

Verifying Quality Control Evaluation Parameters After a Reagent Lot Change

Changing reagent lots can cause a shift in QC results when there is no change in results for patient samples. Because the matrix-related noncommutability between a QC material and a reagent can change with a different reagent lot, QC results are not a reliable indicator of a measurement procedure's performance for patient samples after a reagent lot change. In the example in Fig. 7.7, QC values for the high-concentration control shifted after the change to a new lot of reagents, but there was no change in results for the low control. A comparison of results for a panel of patient samples assayed using the new and old reagent lots showed equivalent results. Consequently, the change in QC values for the high-concentration material was due to a difference in matrix-related noncommutability bias between the QC material and each of the reagent lots.

It is necessary to use patient samples to verify the consistency of results between old and new lots of reagents because of the unpredictability of a matrix-related noncommutability bias being present for QC materials. Fig. 7.8 presents a protocol

Fig. 7.7 Levey-Jennings plot showing impact of a reagent lot change on matrix bias with quality control (QC) samples. (Modified with permission from Miller, W. G., & Nichols, J. H. [2010]. Quality control. In: W. A. Clarke [Ed.], *Contemporary practice in clinical chemistry* [2nd ed.]. Washington, DC: AACC Press.)

to verify or adjust QC material target values after a reagent lot change. A group of patient samples and the QC samples are measured using both the current (old) and new reagent lots. The first step is to verify that results for a group of patient samples measured with the new reagent lot are consistent with results from the current (old) lot. The patient sample results, not the QC results, provide the basis for verifying that the new reagent lot is acceptable for use. If a problem is identified, the calibration of the new reagent lot must be investigated and corrected, or the new reagent lot may be defective and should not be used. When evaluating the patient results, keep in mind that the calibration of the old reagent lot may have drifted and should be verified before concluding that the new reagent lot is not giving acceptable results for the patient samples.

The number of patient samples to use for verifying the performance of a new reagent lot will depend on the measuring interval, the imprecision of a measurement procedure, and the concentrations at which clinical decisions are made. CLSI document EP26 recommends a minimum of three patient samples and more patient samples depending on the number of important clinical decision concentrations and the imprecision of a measurement procedure. This CLSI guideline includes a statistical analysis to determine if a difference in patient results is less than a critical difference that would represent risk for an inappropriate patient care decision based on a particular laboratory test result. An alternate approach is to select 5 to 10 patient samples that span the measuring interval and use a difference plot to evaluate average performance over the interval of concentrations represented by the patient samples. The laboratory must establish acceptance criteria for the agreement of patient results for old and new lot measurements consistent with the relatively small number of samples used, the analytical performance characteristics of a measurement procedure, and the clinical requirements for interpreting results.

When the results for patients are acceptable, the second step in Fig. 7.8 evaluates results for each QC material to

Fig. 7.8 Process for assessment of potential matrix-related noncommutability bias on quality control (QC) samples after a reagent lot change. SD, Standard deviation. (From Miller, W. G. [2016]. *Quality control*. In: *Henry's clinical diagnosis and management by laboratory methods* [23rd ed.]. Philadelphia: Elsevier.)

determine if its target value is correct for use with the new lot of reagent(s). If the target value has changed, it must be adjusted to correct for the change in matrix-related noncommutability bias between old and new lots of reagent(s). This adjustment keeps the expected variability centered around the QC target value so that QC interpretive rules will remain valid.

Failure to make a target value adjustment will cause subsequent QC results to be evaluated incorrectly, as illustrated in Fig. 7.9. The shift in target value would cause some of the results shown by *blue squares* to exceed the old upper QC rule limit, when in reality there is no defect in patient results because the increase in QC results is caused by the matrix-related noncommutability bias with the new reagent lot. Similarly, the increased magnitude of the gap to the old lower QC rule limit will permit a low bias condition, as shown by the *blue square* points at sequence number 29 and 30, to be undetected. In most cases the SD for a QC material will be the same with any lot of reagent(s).

Note that a reagent lot induced matrix-related noncommutability bias change in the numeric values for the QC results will cause an incorrect increase in the cumulative SD if all results are used for the calculation. For this reason, it is recommended to use the cumulative SD from a single reagent lot or the pooled SD from more than one reagent lot when determining the SD to use for interpreting QC rules.

Experience in clinical laboratories has shown that there are changes, other than reagent lot changes, in measurement procedures that can also affect the QC values but not the results for patient samples. Such changes could be caused by instrument component replacement or other causes. In theory, there should be an assignable cause for such effects,

but such a cause is not always identifiable. In practice, any condition that affects QC results but does not affect patient results is treated in the same manner as described for reagent lot changes. The important QC principle is that if the results for patient samples are consistent between the two conditions, then the target value for the QC sample should be adjusted, if necessary, to reflect its value under the new condition. Failure to adjust the QC target value will cause inappropriate acceptability criteria to be used for evaluating the QC results.

Review of Quality Control Data and the Effectiveness of the Quality Control Plan

The immediate use of QC data is to determine if the results for patient samples can be reported for use in clinical care decisions, as described in the preceding sections. In addition, QC data must be reviewed by laboratory management on a regular schedule. Typical review schedules are weekly by senior technologists or supervisors and at least monthly by the laboratory director. However, the laboratory director or supervisor should promptly review items such as reagent or calibrator lot change validations, changes in QC target values associated with reagent lot or other changes, EQA/PT results review, and other occurrences that may affect quality of the laboratory results.

The weekly review process should determine that correct follow-up of any QC alerts was conducted, that all patient samples that may have had erroneous results were repeated, that any corrected reports were issued, and that the process was properly documented in QC records. The monthly review should include any issues identified by the weekly

Fig. 7.9 Illustration of the influence on the failure rate for a quality control (QC) rule when failing to adjust the target value for a matrix-related shift. QC results before a new reagent lot are shown as *gray circles* and after the new reagent lot as *blue squares*. (From Miller, W. G. [2016]. *Quality control*. In: *Henry's clinical diagnosis and management by laboratory methods* [23rd ed.]. Philadelphia: Elsevier.)

review process, as well as examination of the Levey-Jennings chart or a computer-based report, to identify trends or changes in assay performance that may need to be addressed before they have effects on clinical care decisions. Note that automated systems to assist in the review of QC data are acceptable, and individual Levey-Jennings charts do not need to be examined every month. The monthly review should also include any adjustments made to QC parameters or the QC plan for a measurement procedure during the month.

POINTS TO REMEMBER

- Internal QC samples are measured along with patient samples.
- The target value and SD expected for a QC sample are established by the laboratory.
- Results from QC samples are evaluated using interpretive rules that are established after considering the probability for false alerts and the probability for detecting errors that represent a risk of harm to a patient.

EXTERNAL QUALITY ASSESSMENT OR PROFICIENCY TESTING

EQA/PT is used to evaluate measurement procedure performance by comparing a laboratory's results with those of other laboratories for the same set of samples. An EQA/PT provider circulates a set of samples among a group of laboratories that can be several thousand in larger programs. Each laboratory measures the EQA/PT samples as if they were patient samples and reports the results to the EQA/PT provider for evaluation. The EQA/PT provider establishes target values for the EQA/PT samples and determines if the results for an individual laboratory are in close enough agreement with the target

value to be consistent with acceptable measurement procedure performance.

EQA/PT is not available for some analytes because a particular measurement procedure may be new to the clinical laboratory or is not commonly performed or because analyte stability makes it difficult to include in an EQA/PT sample. In these situations the laboratory should use an alternate approach to periodically verify acceptable performance of the measurement procedure. CLSI guideline GP27 provides approaches for verifying measurement procedure performance when formal EQA/PT is not available.

Internal QC material manufacturers may provide a data analysis service that compares results from different laboratories using the same QC material by calculating group statistics for performance evaluation. As with EQA/PT evaluation, this type of interlaboratory QC data analysis allows a laboratory to verify that it is producing QC results that are consistent with those of other laboratories using the same measurement procedure. This information can be helpful for troubleshooting measurement procedure issues and for assessing performance of a new measurement procedure being introduced to a laboratory.

External Quality Assessment or Proficiency Testing Programs That Use Commutable Samples

EQA/PT programs that use commutable samples are preferred whenever available. Commutable samples are typically prepared by using an individual donor's specimen or by pooling clinical patient samples with minimal processing or additives to avoid alteration of the sample matrix. When commutable EQA/PT samples can be prepared, the results reflect what would be expected if individual patient samples were sent to each of the different laboratories. Thus agreement among different laboratories and measurement procedures (harmonization) can be correctly evaluated.

The agreement between an individual laboratory result and a reference measurement result gives an assessment of correct calibration for the laboratory. The agreement between an individual laboratory result and an all-methods mean gives an assessment of harmonization of results with other measurement procedures. The agreement between a measurement procedure group mean value and the reference measurement result gives an assessment of trueness and calibration traceability for the measurement procedure group. In addition, the agreement between a measurement procedure group mean value and an all results mean gives an assessment of harmonization of results. The information for measurement procedure groups is of particular interest to the producers of measurement procedures and can be used as part of a surveillance program for the calibration traceability scheme.

External Quality Assessment or Proficiency Testing Programs That Use Noncommutable Samples

The materials commonly used for EQA/PT samples are derived from blood, urine, or other body fluids but are altered in the process to manufacture EQA/PT samples such that the matrix is modified and the samples frequently do not have the same measurement characteristics as observed for unaltered clinical patient samples. In addition, some EQA/PT samples (e.g., urine, cerebrospinal fluid, or blood gas) are prepared as synthetic materials that are not derived from patient fluids. Consequently, many EQA/PT samples, as for QC samples, are noncommutable with authentic patient samples. The results for a noncommutable EQA/PT sample will have a different relationship in their numeric values between different measurement procedures and sometimes for different reagent lots within a measurement procedure than would be observed for patient samples.

It is a common practice for EQA/PT providers to organize results for noncommutable samples into “peer groups” of measurement procedures that represent similar technology expected to have the same result for a noncommutable EQA/PT sample. The mean or median value of the peer group results is the target value. Because the peer group mean value may be influenced by a matrix-related noncommutability bias, that mean value can be used only to evaluate laboratories using the same or very similar measurement procedures and cannot be used to evaluate laboratories using other measurement procedures or to evaluate if results from different measurement procedures agree with each other. If an individual laboratory’s results agree with those of the peer group, the individual laboratory can conclude that the measurement procedure was performing in conformance with the manufacturer’s specifications. An individual laboratory cannot use results for noncommutable EQA/PT samples to verify that a measurement procedure is calibrated correctly to be traceable to the reference system for an analyte.

However, even within a peer group using the same measurement procedure, differences can occur because of different reagent lots used by the measurement procedures in

different laboratories because the matrix of the EQA/PT material can influence the results from different reagent lots when the patient samples give similar results. Therefore, in some cases, reagent lots should be registered as part of the EQA/PT reporting, and even reagent lot-specific target values may need to be assigned.

Reporting External Quality Assessment or Proficiency Testing Results When One Measurement Procedure Is Adjusted to Agree With Another Measurement Procedure

It is good laboratory practice to adjust the calibration of different measurement procedures for the same measurand used within a large hospital system that can have several satellite laboratories or within a collection of several hospitals with the same management structure, so that the results for patient samples are consistent, irrespective of which measurement procedure is used. Such harmonization of results is important for uniform use of reference intervals and decision thresholds within a hospital or clinic system. It is important to report EQA/PT results such that they can be properly evaluated against the peer group target value. The peer group target value will reflect the measurement procedure calibration established by the measurement procedure manufacturer. For an individual laboratory’s EQA/PT result to be evaluated against the peer group mean, that individual result must be reported to the EQA/PT provider after removing any calibration adjustments so that the reported result is consistent with the manufacturer’s nonadjusted calibration.

The most convenient way to remove a calibration adjustment is to first measure the EQA/PT samples with the calibration adjustment applied to the measurement procedure, as would be the usual measurement process for patient samples. After the measurement, the EQA/PT results should be adjusted “in reverse” by mathematically removing the calibration adjustment factors, and the results should be reported to the EQA/PT provider with any adjustment factors removed. One should not recalibrate the instrument with a new set of calibrators for the purpose of measuring the EQA/PT samples because this practice would violate regulations requiring the EQA/PT material to be measured in the same manner as patient samples. This process permits the EQA/PT sample to be measured in the same manner as patient samples and the numeric result reported to the EQA/PT provider to reflect the actual measured result using the manufacturer’s calibration settings.

Interpretation of External Quality Assessment or Proficiency Testing Results

Many countries have regulations requiring EQA/PT and specifying the evaluation criteria for acceptable performance. When criteria are set by regulations, an EQA/PT provider is required to use them. When criteria are not set by regulations, the EQA/PT provider sets evaluation criteria on the basis of clinically acceptable performance, biological

variation, or the analytical capability of the measurement procedures in use. EQA/PT evaluation criteria are usually designed to evaluate the total error of a single measurement. In some programs, measurements are made several times, and it is possible to separately assess the bias and the imprecision. The acceptability limits for EQA/PT include bias and imprecision components considered acceptable for clinical use of a result, plus other error components that are unique to EQA/PT samples such as between-laboratory variation in calibration; variable matrix-related noncommutability bias with different lots of reagent within a peer group; uncertainty in the target value; stability variability in the EQA/PT material, both in storage and shipping, and after reconstitution or opening in the laboratory; and homogeneity of the EQA/PT material vials. Consequently, the acceptability limits for EQA/

PT samples are frequently larger than what might be expected for clinically acceptable total error with patient samples.

Fig. 7.10 is an example of a typical evaluation report sent to a participating laboratory. Each reported result is compared with the mean result for the peer group using the same measurement procedure. The report also includes the SD for the distribution of results in the peer group, the number of laboratories in the peer group, and the SDI (also called a z-score), which expresses the reported result as the number of SDs it is from the mean value ($SDI = [\text{result} - \text{mean}]/SD$). The limits of acceptability are shown. Acceptability criteria may be a number of SDs from the mean value, a fixed percent from the mean value, or a fixed concentration from the mean value. For example, in **Fig. 7.10**, calcium acceptability criteria are

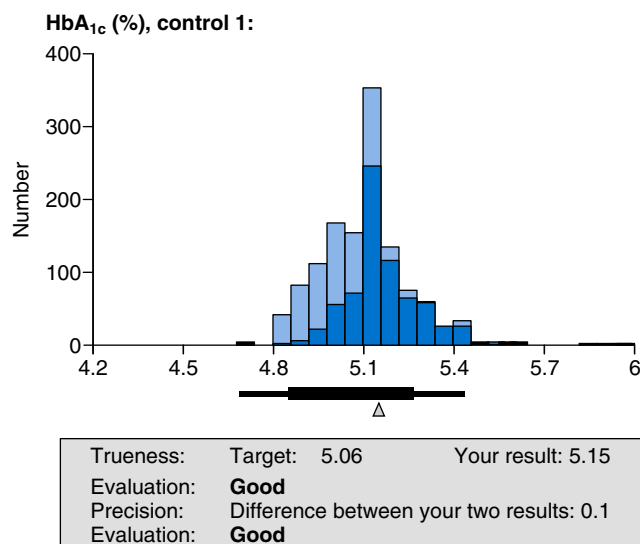

Fig. 7.11 Example of part of a feedback report to hemoglobin A_{1c} (HbA_{1c}) point-of-care (POC) users in a survey for general practitioners' offices and nursing homes. Commutable external quality assessment/proficiency testing material was circulated in two levels and measured in duplicate. The participant is informed about the bias (mean of the two results) compared with a reference measurement procedure target (*x*-axis) and "precision" as the difference between the two results. The histogram represents the distribution of results among all participants (*light blue*) and for the participant's method group (*dark blue*). The thick black line represents the interval for "good" results, and the thin black line represents the interval for "acceptable" results. Results outside these limits are characterized as "poor." The triangle points to the result of the participant. (Modified with permission from the Norwegian Quality Improvement of Primary Care Laboratories, the external quality assessment provider in Norway.)

± 1 mg/dL (0.25 mmol/L) from the mean value, and iron criteria are $\pm 20\%$ from the mean value.

In Fig. 7.10 the calcium results are in close agreement with the peer group mean (SDI ranges from -0.2 to -1.4), and the laboratory can conclude that its results are consistent with those of others in the peer group using the same measurement procedure and that it is using the measurement procedure according to the manufacturer's specifications. However, the iron results show greater variability, with one result $+3.5$ SDI. Although all iron results are within the acceptability criteria, it is recommended to investigate the measurement procedure because a $+3.5$ SDI is more likely to be different from other participants in the peer group than to be in agreement with them.

Fig. 7.11 shows another type of evaluation report sent to a primary care office for hemoglobin A_{1c} (HbA_{1c}) for one of two EQA/PT samples. In this situation the EQA/PT provider is communicating directly with the clinician or the coworker in the general practice office, and the feedback must be easy to understand for nonlaboratory professionals. The EQA/PT result is evaluated as "good," "acceptable," or "poor." The lot numbers of the reagent are registered so that the participant, in case of an aberrant result, can

get information if the result was due to the measurement procedure used, the reagent lot used, or the performance of the user.

Fig. 7.12 shows a similar report from the same HbA_{1c} survey provided to hospital laboratories. In addition to the figures about the distribution of results, information is provided on how different measurement procedures performed, as well as a historical overview of performance on consecutive EQA/PT samples and performance related to the concentration of the sample. The EQA/PT material used for the HbA_{1c} is pooled fresh patient blood (commutable), and the target value is set by a reference measurement procedure and is therefore the same for all measurement procedures. Each sample was measured in duplicate (as requested by the EQA/PT provider), and the mean of the duplicate was used to estimate bias versus the reference measurement procedure. In the present example the performance was within the acceptability limits but with a generally high bias during the whole period. Because this observation was true for all the instruments using this measurement procedure, the EQA/PT organizer discussed the results with the manufacturer to solve the problem. Until the problem was solved (the manufacturer had to make a new calibrator), the participants were advised by the EQA/PT provider to use a correction factor when reporting their results for patient samples.

If an unacceptable EQA/PT result is identified, the measurement procedure must be investigated for possible causes and the necessary corrective action taken. Even when an EQA/PT result is within acceptability criteria, it is a good laboratory practice to investigate results that are more than approximately 2.5 SDI from the peer group mean. When the SDI is 2.5, there is only a 0.6% probability that the result will be within the expected distribution for the peer group; consequently, the probability is reasonable that a measurement procedure problem may need to be corrected.

Common causes for EQA/PT failure are listed in Box 7.1. Incorrect handling and reporting are unique to EQA/PT events and may not reflect the process used in the laboratory for patient samples. Because the influence of reagent lots on noncommutability related bias is well documented, a reagent lot-specific bias is a possible explanation when no other root cause can be identified.

POINTS TO REMEMBER

- An independent external organization circulates EQA/PT samples with unknown target values.
- When commutable "patient-like" material is used, a laboratory can compare its results with results from all other measurement procedures and often with a true value from a reference measurement procedure.
- When noncommutable material is used, a laboratory can compare its results only with results from participants in a "peer group" using a similar measurement procedure.

Fig. 7.12 Example of a part of a feedback report to hemoglobin A_{1c} (HbA_{1c}) users in hospital laboratories. Same survey and same materials as presented in Fig. 7.11. The histogram represents the distribution of results among all participants (light blue) and for the participant's method group (dark blue). Only limits for "acceptable" (Acc.) results are given (thin black lines in figures). Information about performance of measurement procedures is given in addition to a historical overview of percentage deviation from target values dependent on time and concentration of HbA_{1c}. CV, Coefficient of variation; HPLC, high-pressure liquid chromatography; SD, standard deviation. (Modified with permission from the Norwegian Quality Improvement of Primary Care Laboratories, the external quality assessment provider in Norway.)

BOX 7.1 Classification of Potential Problems Identified When Investigating Unacceptable External Quality Assessment or Proficiency Testing Results

1. Clerical errors

Incorrectly transcribed EQA/PT result from the instrument read-out to the report form
The EQA/PT sample was mislabeled in the laboratory
Incorrect instrument or measurement procedure was reported on the results submission form
Incorrect units were reported
Decimal point was misplaced

2. Measurement procedure problems

Inadequate SOP
Problem with manufacture or preparation of reagents or calibrators (e.g., unstable)
Lot-to-lot variation in reagents or calibrators
Incorrect value assignment of calibrators
Measurement procedure lacks adequate specificity for the measurand
Measurement procedure lacks adequate sensitivity to measure the concentration
Carry-over from a previous sample
Inadequate QC procedures used

3. Equipment problems

Obstruction of instrument tubing or orifice by clot
Misalignment of instrument probes
Incorrect instrument data processing functions
Incorrect instrument setting
Automatic pipetter not calibrated to acceptable precision and accuracy

Equipment component malfunction (e.g., light source, membrane, fluidics, detector)
Incorrect instrument conditions (e.g., water quality, surrounding temperature)
Instrument maintenance not performed appropriately

4. Technical problems caused by personnel errors

Did not operate equipment correctly or did not conform to measurement procedure SOP
Incorrect storage, preparation, or handling of reagents or calibrators
Delay causing evaporation or deterioration of the EQA/PT sample
Failure to follow recommended instrument function checks or maintenance
Pipetting or dilution error
Calculation error
Misinterpretation of test result

5. A problem with the EQA/PT material such as:

Incorrect storage, preparation, or handling of EQA/PT materials
Differences between EQA/PT samples and patient samples (e.g., matrix, additives, stabilizers)
Sample deteriorated in transit or during laboratory storage
Sample had weak or borderline reaction
Sample contained interfering factors (which may be measurement procedure specific)
Sample was not homogeneous among vials

^aThis classification scheme assists in developing an appropriate corrective action plan.

EQA, External quality assessment; PT, proficiency testing; QC, quality control; SOP, standard operating procedure.

From Miller, W. G., Jones, G. R. D., Horowitz, G. L., & Weykamp, C. (2011). Proficiency testing/external quality assessment: current challenges and future directions. *Clinical Chemistry*, 57, 1670–1680.

REVIEW QUESTIONS

1. Why should internal quality control be performed?
 - a. To be sure that the quality control material is of good quality
 - b. To examine if the control material is commutable—behaves like patient samples
 - c. To have a high probability that correct patient results are released
 - d. To be able to pass the accreditation inspection
 - e. To examine if my measurement procedure gives results similar to other laboratories
2. How should I interpret results when an EQA/PT program uses noncommutable materials?
 - a. When my result is within the performance specifications, I can be confident that I have no bias compared with a true value.
 - b. When my result is outside the performance specifications, I have to recalibrate my measurement procedure.
 - c. When my result is close to the target value for the peers in my measurement procedure group, I can be confident my laboratory is performing as well as my peers.
 - d. I should compare my results with results from other measurement procedures to be confident my laboratory is not biased.
 - e. I should compare my results with the average of all measurement procedure groups.
3. What is the advantage of using commutable EQA/PT materials?
 - a. They are similar to patient samples and should therefore not be used for QC.
 - b. They are suitable for internal quality control but not for EQA/PT.
 - c. They should be avoided since they are contagious.
 - d. Their results provide information on the accuracy for patient samples if the target value is set by a reference measurement procedure.
 - e. Their results can be compared among different measurement procedures to assess harmonization.
4. When should EQA/PT be used?
 - a. To decide if patient results can be released
 - b. Should be performed every second day

- c. To assess the performance of your measurement procedure compared with other measurement procedures
 - d. Only when the provider uses commutable material
 - e. Is not necessary if you have documented traceability of your measurement procedure
5. How is the SD estimated for an internal QC material?
- a. From measurements made during the target value assignment of a QC material
 - b. From the long-term SD that includes most types of variability expected to influence the measurement procedure
 - c. From the instructions for use provided by the measurement procedure manufacturer
 - d. From reports of interlaboratory summaries
 - e. From the range of acceptable results provided by the QC material manufacturer

Principles of Basic Techniques and Laboratory Safety

Stanley Lo*

OBJECTIVES

1. Define the following:
 - Analyte
 - Centrifugation
 - Dilution
 - Evaporation
 - Filtration
 - Gravimetry
 - Lyophilization
 - Primary/Secondary reference material
 - Relative centrifugal force/field (RCF)
 - Solution
 - Standard precautions
2. Describe three methods of preparing reagent grade water; identify the criteria for determining when the purification process for Clinical Laboratory Reagent Grade Water is considered acceptable.
3. List and compare the different grades of reagents available, and state which are appropriate for use in a clinical laboratory.
4. Compare the two types of reference materials used in the clinical laboratory, and state the specific uses of each type.
5. List and describe three types of pipettes used in the clinical laboratory; state the proper use and the specific uses of each type.
6. For the process of centrifugation:
 - State the principle.
 - List six uses of centrifugation in the clinical laboratory.
 - Calculate RCF and revolutions per minute (rpm) when given the appropriate information.
 - Determine the time required for centrifugation using an alternate rotor.
 - Outline proper operation and operation practice of a centrifuge.
7. Describe three types of balances used in the clinical laboratory and how they are calibrated.
8. Compare serial dilutions with simple dilutions; state and calculate the formula used to prepare a solution of lesser concentration from one of greater concentration.
9. List and describe the elements of an Occupational Safety and Health Administration (OSHA)-approved chemical hygiene plan, a hazard exposure plan, and a tuberculosis control plan; describe the Standard Precautions document, including source and specific mandates; state the College of American Pathologists (CAP) requirements for a laboratory ergonomics program.
10. For the following hazard types, interpret laboratory hazard signage, and state the appropriate work practice used to control these hazards:
 - Biological
 - Chemical
 - Electrical
 - Fire

KEY WORDS AND DEFINITIONS

Analyte A solute dispersed in a solution that is measured in laboratory practice; also referred to as a *measurand*.

Buffer solution A solution that contains either a weak acid and its salt or a weak base and its salt and is resistant to changes in pH.

Centrifugation The process of using centrifugal force to separate the lighter portions of a solution from the heavier portions; a centrifuge is a device by which centrifugation is affected.

Chemical hygiene plan (CHP) An Occupational Safety and Health Administration (OSHA)-required listing of responsibilities for laboratory employers, employees, and a chemical hygiene officer, and including a complete chemical inventory that is updated annually, along with a copy of the Material Safety Data Sheet (MSDS) that defines each chemical as toxic, carcinogenic, or dangerous, and that must be on file and available to all employees 24 hours a day, 7 days a week.

*The author gratefully acknowledges the original contributions of Drs. Edward W. Bermes, Stephen E. Kahn, Donald S. Young, Edward R. Powsner, and John C. Widman, on which portions of this chapter are based.

Clinical and Laboratory Standards Institute

(CLSI) The CLSI (formerly the National Committee for Clinical Laboratory Standards, or NCCLS) that guides the development and implementation of standards and guidelines that help all laboratories fulfill their goals.

Ergonomics The study of capabilities in relationship to work demands completed by defining postures that minimize unnecessary static work and reduce the forces working on the body.

Exposure control plan An OSHA-required plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens, while ensuring that medical wastes produced by the clinical laboratory are managed and handled in a safe and effective manner.

Material Safety Data Sheet (MSDS) A technical bulletin that contains information about a hazardous chemical, such as chemical composition, chemical and physical hazard, and precautions for safe handling and use.

Measurand See *Analyte*.

OSHA Occupational Safety and Health Administration, formed by the federal government of the United States to formally regulate the oversight of employee safety.

Pipette Device used for the transfer of a volume of liquid from one container to another.

Reagent Chemical used in many high-purity applications.

Reference material A material or substance, one or more physical or chemical properties of which are sufficiently well established to be used for the calibration of an apparatus, the verification of a measurement method, or the assigning of values to materials. Certified, primary, and secondary are types of reference materials.

Relative centrifugal force or field (RCF) Force required to separate two phases (liquid and solid) in a centrifuge.

Standard precautions Approach to infection control that treats all human blood and certain human body fluids as if they were known to be infectious for bloodborne pathogens.

An understanding of basic principles and techniques of analytical chemistry is necessary to appropriately interpret clinical laboratory tests and adequately validate assays. These are integral to understanding basic laboratory tasks such as making **buffer solutions**, performing dilutions, evaporation, and filtration. Safety is a constant concern for laboratory personnel. A comprehensive safety program consisting of a plan for the handling of chemicals, exposure to bloodborne pathogens, tuberculosis (TB), and other highly infectious agents, as well as training to handle various types of hazards is essential.

CHEMICALS

The quality of the analytical results produced by the laboratory is directly affected by the purity of the chemicals used as analytical **reagents**. The availability and quality of the reference materials used to calibrate assays and to monitor their analytical performance are also important.

Laboratory chemicals are available in a variety of grades. The solutes and solvents used in analytical work are **reagent grade chemicals**, among which water is a solvent of primary importance.

Reagent Grade Water

Preparation of many reagents and solutions used in the clinical laboratory requires “pure” water. Single-distilled water fails to meet the specifications for Clinical Laboratory Reagent Water (CLRW) established by the **Clinical and Laboratory Standards Institute (CLSI)**. Because the terms *deionized water* and *distilled water* describe preparation techniques,

they should be replaced by reagent grade water, and if appropriate, followed by the designation of CLRW, which better defines the specifications of the water and is independent of the method of preparation (Table 8.1).

TABLE 8.1 Clinical and Laboratory Standards Institute Specifications for Clinical Laboratory Reagent Water

	CLRW
Microbiological content ^a (cfu/mL) (maximum)	<10
Resistivity ^b (MΩ/cm), 25°C	≥10
Particulate matter ^c	Water passed through 0.22-μm filter
Total organic content (ng/g)	<500

CLRW, Clinical Laboratory Reagent Water.

^aMicrobiological content. The microbiological content of viable organisms, as determined by total colony count after incubation at 36 ± 1°C for 14 h, followed by 48 h at 25 ± 1°C, and reported as colony-forming units per milliliters (cfu/mL).

^bSpecific resistance or resistivity. The electrical resistance in ohms measured between opposite faces of a 1-cm cube of an aqueous solution at a specified temperature. For these specifications, the resistivity will be corrected for 25°C and reported in megohms per centimeters (MΩ/cm). The higher the quantity of ionizable materials, the lower will be the resistivity and the higher the conductivity.

^cParticulate matter. When water is passed through a membrane filter with a mean pore size of 0.22 μm, nearly all microorganisms and particulates are removed.

From Clinical and Laboratory Standards Institute. (2006). *Preparation and testing of reagent water in the clinical laboratory* (4th ed.). CLSI Document GP40-A4-AMD. Wayne, PA: CLSI.

Preparation of Reagent Grade Water

Distillation, ion exchange, reverse osmosis, and ultraviolet (UV) oxidation are processes used to prepare reagent grade water. In practice, water is filtered before any of these processes are used.

Distillation. Distillation is the process of vaporizing and condensing a liquid to purify or concentrate a substance or to separate a volatile substance from less volatile substances. It is the oldest method of water purification. Problems with distillation for preparing reagent water include the carryover of volatile impurities and entrapped water droplets that may contain impurities into the purified water. This results in contamination of the distillate with volatiles, sodium, potassium, manganese, carbonates, and sulfates. As a result, water treated by distillation alone does not meet the specific conductivity requirement of CLRW.

Ion exchange. Ion exchange is a process that removes ions to produce mineral-free deionized water. Such water is most conveniently prepared using commercial equipment, which ranges in size from small, disposable cartridges to large, resin-containing tanks. Deionization is accomplished by passing feed water through columns containing insoluble resin polymers that exchange hydrogen (H^+) and hydroxide (OH^-) ions for the impurities present in the ionized form in the water. The columns may contain cation exchangers, anion exchangers, or a *mixed-bed resin exchanger*, which is a mixture of cation- and anion-exchange resins in the same container.

A single-bed deionizer generally is capable of producing water that has a specific resistance in excess of 1 $M\Omega/cm$. When connected in series, mixed-bed deionizers usually produce water with a specific resistance that exceeds 10 $M\Omega/cm$.

Reverse osmosis. Reverse osmosis is a process by which water is forced through a semipermeable membrane that acts as a molecular filter. The membrane removes 95% to 99% of organic compounds, bacteria, other particulate matter, and 90% to 97% of all ionized and dissolved minerals, but has fewer of the gaseous impurities. Although this process is inadequate for producing reagent grade water for the laboratory, it may be used as a preliminary purification method.

Ultraviolet oxidation. UV oxidation is another method that works well as part of a total system. The use of UV radiation at the biocidal wavelength of 254 nm eliminates many bacteria and cleaves many ionizing organics that are then removed by deionization.

Quality, Use, and Storage of Purified Water

Autoclave or wash water (formerly type III water) may be used for glassware washing. However, final rinsing should be done with the water grade suitable for the intended glassware use. It may also be used for certain qualitative procedures, such as those used in general urinalysis. A variety of purification processes can be used to produce this type of water.

The CLRW, formerly described as type I or II water, is used for most routine clinical laboratory testing. Purification processes for CLRW must achieve specific targets for microbial

content, resistivity, particulate matter, and total organic content (see Table 8.1). Storage and delivery systems should be constructed to ensure a minimum of chemical or bacterial contamination. The frequency of monitoring of water specifications and the purification system is to be determined by each laboratory.

Special reagent water is used for specific applications. At a minimum, the water should meet CLRW specifications; however, additional parameters may be needed for certain applications. For example, water used for DNA and RNA testing may have specifications for protease and nuclease activity. Water used in trace metal analysis should contain minimally detectable amounts of each metal being measured.

POINTS TO REMEMBER

Water

- There are several types of water used in the clinical laboratory, including CLRW, special reagent water, and autoclave and wash water. CLRW has specifications for its microbiological content, resistivity, particulate matter, and total organic content.
- The monitoring of water depends on the type of water and its intended use.

Testing for Water Purity

At a minimum, water should be tested for microbiological content, particulates, resistivity, and total organic content. Protocols for testing the purity of water can be found in CLSI GP40-A4-AMD:2012. The frequency of monitoring water purity should be established by the laboratory, such that water purity is maintained for its intended purpose. It should be noted that measurements taken at the time of production may differ from those taken at the time and place of use. For example, if the water is piped a long distance, consideration must be given to deterioration en route to the site of use. To meet the specifications for high-performance liquid chromatography (HPLC), in some instances it may be necessary to add a final 0.1- μm membrane filter. The water can be tested by HPLC using a gradient program and monitored with an UV detector. No peaks exceeding the analytical noise of the system should be found.

Reagent-Grade or Analytical Reagent-Grade Chemicals

Chemicals that meet specifications of the American Chemical Society are described as reagent or analytical reagent grade. These specifications have also become the de facto standards for chemicals used in many high-purity applications. These are available in two forms: (1) lot-analyzed reagents, in which each individual lot is analyzed and the actual amount of impurity reported, and (2) maximum impurities reagents, for which maximum impurities are listed. The Committee on Analytical Reagents of the American Chemical Society periodically publishes "Reagent Chemicals," which is a list of specifications (<http://pubs.acs.org/reagents/index.html>). These reagent-grade chemicals are of very high purity and are recommended for quantitative or qualitative analyses.

Ultrapure Reagents

Many analytical techniques require reagents whose purity exceeds the specifications of those described previously. Manufacturers offer selected chemicals that have been especially purified to meet specific requirements. There is no uniform designation for these chemicals and organic solvents. Terms such as *spectrograde*, *nanograde*, and *HPLC pure* have been used. Data of interest to the user (e.g., absorbance at a specific UV wavelength) are supplied with the reagent.

Other designations of chemical purity include chemically pure (CP), US Pharmacopeia (USP), and National Formulary (NF) grade (chemicals produced to meet specifications set down in the USP or the NF). Chemicals labeled purified, practical, technical, or commercial grade should not be used in clinical chemical analysis without previous purification.

REFERENCE MATERIALS

A **reference material** is a material or substance with one or more physical or chemical properties that is sufficiently well established to be used for (1) calibrating instruments, (2) validating methods, (3) assigning values to materials, and (4) evaluating the comparability of results. Reference materials are of prime importance in establishing *metrologic transferability* (<http://www.bipm.org>), a term defined as “the property of a measurement result whereby the result can be related to a reference through a documented unbroken chain of calibrations, each contributing to the measurement uncertainty.”

Primary, secondary, standard, and certified are types of reference materials.

Primary Reference Materials

Primary reference materials are highly purified chemicals that are directly weighed or measured, and dissolved in a solvent with an exactly measured total volume after the chemical has gone completely into solution, to produce a solution whose concentration is exactly known. The International Union of Pure and Applied Chemistry (IUPAC) has proposed a degree of 99.98% purity for primary reference materials. These highly purified chemicals may be weighed out directly for the preparation of solutions of selected concentration or for the calibration of solutions of unknown strength. They are supplied with a certificate of analysis for each lot.

Secondary Reference Materials

Secondary reference materials are solutions whose concentrations cannot be prepared by weighing the solute and dissolving a known amount into a volume of solution. The concentration of secondary reference materials is usually determined by analysis of an aliquot of the solution by an acceptable reference method, using a primary reference material to calibrate the method.

Standard Reference Materials

Standard reference materials (SRMs) for clinical and molecular laboratories are available from the National Institute of Standards and Technology (NIST; <http://www.nist.gov>).

Cholesterol, the first SRM developed by the NIST, was issued in 1967. It should be noted that not all SRMs have the properties and the degree of purity specified for a primary standard, but each has been well characterized for certain chemical or physical properties and is issued with a certificate that provides results of the characterization. These may then be used to characterize other materials.

Certified Reference Materials

Certified reference materials (CRMs) are available for clinical and molecular laboratories from the Institute for Reference Materials and Measurements (IRMM) in Geel, Belgium (<http://www.irmm.jrc.be>). The IRMM is one of the seven institutes of the Joint Research Centre (JRC), a Directorate-General of the European Commission (EC). Other acronyms used to label IRMM reference materials include ERM (European Reference Materials) and BCR (Community Bureau of Reference of the Commission of the European Communities). Reference materials are also available from the World Health Organization (WHO; <http://www.who.int/biologicals>).

POINTS TO REMEMBER

Ultrapure Reagents

There are several types of ultrapure reagents. For the clinical laboratory, they are referred to as reference materials. There are several different types of reference materials:

- Primary reference materials
- Secondary reference materials
- Standard reference materials
- Certified reference materials

BASIC TECHNIQUES AND PROCEDURES

Basic practices used in clinical laboratories include (1) optical, (2) chromatographic, (3) electrochemical, (4) electrophoretic, (5) mass spectrometric, (6) enzymatic, and (7) immunoassay techniques. These techniques are discussed in detail in Chapters 9 through 15. This chapter discusses the basic techniques of volumetric sampling and dispensing, centrifugation, measurement of radioactivity, gravimetry, thermometry, and processing solutions.

Volumetric Sampling and Dispensing

Clinical chemistry procedures require accurate volumetric measurements to ensure accurate results. For accurate work, only class A glassware should be used. Class A glassware is certified to conform to the specifications outlined in NIST circular C-602.

Pipettes

Pipettes are used for the transfer of a volume of liquid from one container to another. They are designed either (1) to contain a specific volume of liquid or (2) to deliver a specified volume. Pipettes used in clinical laboratories include (1) manual transfer and measuring pipettes, (2) micropipettes, and (3) electronic and mechanical pipetting devices. Developments

Fig. 8.1 Pipettes. (A) Volumetric (transfer); (B) Ostwald-Folin (transfer); (C) Mohr (measuring); (D) Serologic (graduated to the tip).

in improved design of pipetting systems include robotic automation, the capability to provide electronic and personal computer control of pipetting devices, and careful attention to advanced ergonomic design features. Automatic photometric pipette calibration systems are also available that reduce the time needed to periodically check pipettes and potentially allow more efficient use of personnel.

Transfer and measuring pipettes. A transfer pipette is designed to transfer a single known volume of liquid. Measuring and serologic pipettes are scored in units such that any volume up to a maximum capacity is delivered.

Transfer pipettes. Transfer pipettes include both volumetric and Ostwald-Folin pipettes (Fig. 8.1). They consist of a cylindrical bulb joined at both ends to narrower glass tubing. A calibration mark is etched around the upper suction tube, and the lower delivery tube is drawn out to a gradual taper. The bore of the delivery orifice should be sufficiently narrow to allow rapid outflow of liquid, without incomplete drainage causing measurement errors beyond the specified tolerances.

A volumetric transfer pipette (see Fig. 8.1A) is calibrated to accurately deliver a fixed volume of a dilute aqueous solution. The reliability of the calibration of the volumetric pipette decreases with decreased size, and therefore special micropipettes have been developed.

Ostwald-Folin pipettes (see Fig. 8.1B) are similar to volumetric pipettes, but they have the bulb closer to the delivery tip and are used for accurate measurement of viscous fluids, such as blood or serum. In contrast to a volumetric pipette, an Ostwald-Folin pipette has an etched ring near the mouthpiece, indicating that it is a blow-out pipette. Using a pipetting bulb, the liquid is blown out of the pipette only after the blood or serum has drained to the last drop in the delivery tip. When filled with opaque fluids, such as blood, the top of the meniscus must be read. Controlled slow drainage is required with all viscous solutions so that no residual film is left on the walls of the pipette.

Measuring pipettes. The second principal type of pipette is the graduated or measuring pipette (see Fig. 8.1C). This is a piece of glass tubing that is drawn out to a tip and graduated uniformly along its length. Two types are available. The Mohr pipette is calibrated between two marks on the stem, whereas the serologic pipette has graduated marks down to the tip. The serologic pipette (see Fig. 8.1D) must be blown out to deliver the entire volume of the pipette and has an etched ring (or pair of rings) near the bulb end of the pipette, signifying that it is a blow-out pipette. Mohr pipettes require controlled delivery of the solution between the calibration marks. Serologic pipettes have a larger orifice than do Mohr pipettes and thus drain faster. In practice, measuring pipettes are used principally for measurement of reagents and generally are not considered sufficiently accurate for measuring samples and calibrators.

Pipetting technique. There are general pipetting techniques that apply to the pipettes described previously. For example, pipetting bulbs should always be used, and pipettes must be held in a vertical position when the liquid level is adjusted to the calibration line and during delivery. The lowest part of the meniscus, when it is sighted at eye level, should be level with the calibration line on the pipette. The flow of liquid should be unrestricted when volumetric pipettes are used, and the tips should be touched to the inclined surface of the receiving container for 2 seconds after the liquid has ceased to flow.

With graduated pipettes, the flow of liquid may have to be slowed during delivery. Serologic pipettes are calibrated to the tip, and the etched glass ring on top of the pipette signifies that it is to be blown out. First, the pipette is allowed to drain, and then the remaining liquid is blown out.

Micropipettes. Micropipettes are pipettes used for the measurement of microliter volumes. With such devices, the remaining volume that coats the inner wall of a pipette causes notable error. For this reason, most micropipettes are calibrated to contain the stated volume rather than to deliver it. Proper use requires rinsing the pipette with the final solution after the contents are delivered into the diluent. Volumes are expressed in microliters (μL); the older term *lambda* is no longer recommended. Micropipettes generally are available in small sizes, ranging from 1 to 1000 μL ; also, they are available for volumes as low as 0.2 μL .

Semiautomatic and automatic pipettes and dispensers. Fig. 8.2A and B, illustrate two types of adjustable micropipetting devices that demonstrate unique ergonomic design features. These devices are programmable and are used with disposable plastic tips for simultaneously dispensing aliquots of liquid into multiple wells. Each channel is piston driven to allow the user to pipette with as few or as many tips as necessary. Aliquots of liquid as small as 0.2 μL are dispensed at three different aspiration or dispense rates.

Semiautomatic manual and electronic versions of pipettes and dispensers are available in sizes ranging from 0.5 μL to 10 mL or larger. Fig. 8.2C illustrates an electronically operated, positive-displacement multichannel pipettor. This device aspirates and dispenses its predefined volumes (from 0.5 to

Fig. 8.2 (A) Adjustable volume micropipetting device with ergonomic design. (B) Adjustable volume electronic micropipetting device with ergonomic design. (C) Electronic programmable multichannel pipette. ([A] Courtesy Biohit Plc.; [B] Courtesy Vistalab Technologies, Inc.; [C] Courtesy Rainin Instrument LLC.)

200 μL) when its plunger is moved through a complete cycle. Its disposable, fluid containment tips are made of a plastic material that tends to retain less inner surface film than does glass. Such pipettes (1) avoid the risk of cross-contamination among samples, (2) eliminate the necessity for washing between samples, and (3) improve the precision of measurements. Models that allow for digital adjustment of the volume aspirated and dispensed are available.

Fig. 8.3A shows an automatic dispensing apparatus that aspirates and dispenses preset volumes of two different liquids by two motor-driven syringes, one for metering a volume of the sample and one for metering a volume of the diluent. It is possible to adjust this device to aspirate as little as 1 μL of one liquid and to deliver it with as much as 999 μL of the other. This type of device, available as a dilutor or dispenser, is obtainable as a manual, electronic, or computer-controlled device. The device is microprocessor-controlled and is easily programmed.

A more versatile piece of equipment is the robotic liquid handling workstation shown in Fig. 8.3B. This automated pipetting station is used with individual reaction tubes and also with 96- and 384-well microtiter plates. Depending on the design of the

system, a single probe or multiple probes may be used to rapidly transfer programmed volumes of solution from one container to microtiter plates (e.g., so that the transfer to all 96 wells is complete in 1 minute). In some systems, liquid sensing is incorporated into the sample probes to minimize contact with sample and reagents, although automatic washing of the probes is performed between specimens. Two-dimensional (X-Y) movement of probes and tubes or microtiter plates is built into the pipetting stations to minimize the necessity for operator intervention. This device dispenses programmed volumes from 0.5 to 1000 μL in serial dilutions from 4 to 16 channels using an autoloading system with barcodes for positive identification.

Volumetric Flasks

Volumetric flasks (Fig. 8.4) are used to measure exact volumes; they are commonly found in sizes varying from 1 to 4000 mL. In practice, they are used primarily to prepare solutions of known concentration, and they are available in various grades. The most accurate are certified as meeting standards set forth by the NIST.

An important factor in the use of a volumetric apparatus is the requirement for an accurate adjustment of the meniscus.

A

B

C

Fig. 8.3 (A) Personal computer-controlled diluting and/or dispensing apparatus that aspirates and dispenses preset volumes of one or two different liquids, such as a diluent and sample, by motor-driven syringes. (B and C) Robotic liquid handling workstations. ([A and B] Courtesy Hamilton Co.)

A

B

Fig. 8.4 Volumetric Flasks. (A) Macro; (B) Micro.

A small piece of card that is half black and half white is most useful. The card is placed 1 cm behind the apparatus, with the white half uppermost and the top of the black area approximately 1 mm below the meniscus. The meniscus then appears as a clearly defined, thin black line. This device is also useful in reading the meniscus of a burette.

Volumetric equipment should be used with solutions equilibrated to room temperature. Solutions diluted in volumetric flasks should be repeatedly mixed during dilution so that the contents are homogeneous before the solution is made up to final volume. Errors caused by expansion or contraction of liquids upon mixing are thereby minimized.

Volumetric flasks should be thoroughly cleaned and dried before calibration. The flask is then weighed and filled with carbon dioxide-free deionized water until just above the graduation mark. The neck of the flask just above the water level should be kept free of water. The meniscus mark is set at the graduation line by removing excess water, and the flask is reweighed. The final weight is corrected for the equilibrated water and air temperature to obtain the volume of the flask. Flasks also may be calibrated by the spectrophotometric technique described in the next section.

Centrifugation

Centrifugation is the process of using centrifugal force to separate the lighter portions of a solution, mixture, or suspension from the heavier portions. A centrifuge is a device by which centrifugation is performed.

In the clinical laboratory, centrifugation is used to:

1. Remove cellular elements from blood to provide cell-free plasma or serum for analysis (see [Chapter 6](#)).
2. Concentrate cellular elements and other components of biological fluids for microscopic examination or chemical analysis.

3. Remove chemically precipitated protein from an analytical specimen.
4. Separate protein- or antibody-bound ligand from free ligand in immunochemical and other assays (see [Chapter 15](#)).
5. Extract solutes in biological fluids from aqueous to organic solvents.
6. Separate lipid components (e.g., chylomicrons) from other components of plasma or serum, and lipoproteins from one another (see [Chapter 23](#)).

Types of Centrifuges

Several types of centrifuges are used in the clinical laboratory, including (1) horizontal head, (2) swinging bucket, (3) fixed-angle head, (4) angle head, (5) ultracentrifuge, and (6) axial units. In addition, the development of automatic balancing centrifuges has enabled centrifugation to be incorporated as an integral step in the total automation of laboratory testing (see [Chapter 16](#)).

Principles of Centrifugation

The correct term to describe the force required to separate two phases in a centrifuge is **relative centrifugal force (RCF)**. Units are expressed as number of times greater than gravity (e.g., $500 \times g$).

RCF is calculated as follows:

$$\text{RCF} = 1.118 \times 10^{-5} \times r \times \text{rpm}^2$$

where 1.118×10^{-5} = empirical factor; r = radius in centimeters from the center of rotation to the bottom of the tube in the rotor cavity or bucket during centrifugation; and rpm = the speed of rotation of the rotor in revolutions per minute.

The RCF of a centrifuge may also be determined from a nomogram distributed by manufacturers of centrifuges. RCF is derived from the distance from the rotor center to the bottom of the tube, whether the tube is horizontal to, or at an angle to, the rotor center.

The time required to sediment particles depends on the (1) rotor speed, (2) radius of the rotor, and (3) effective path length traveled by the sedimented particles (i.e., the depth of the liquid in the tube). Duplication of conditions of centrifugation is often desirable. The following is a useful formula for calculating the speed required of a rotor whose radius differs from the radius with which a prescribed RCF is originally defined:

$$\begin{aligned} \text{rpm (alternate rotor)} \\ = 1000 \times \sqrt{\frac{\text{RCF, original rotor}}{11.18 \times [r(\text{cm}), \text{alternate rotor}]}} \end{aligned}$$

The length of time for centrifugation is calculated so that running with an alternate rotor of a different size is equivalent to running with the original rotor:

$$\text{time (alternate rotor)} = \frac{\text{time} \times \text{RCF (original rotor)}}{\text{RCF (alternate rotor)}}$$

Note, however, that it may not be possible to reproduce conditions exactly when a different centrifuge is used. Descriptions of times of centrifugation include the time for the rotor to reach operating speed (which may vary from instrument to instrument) and do not include deceleration time, during which sedimentation is still occurring but is doing so less efficiently. Even with maximal braking, deceleration may take as long as 3 minutes in some centrifuges.

Operation of the Centrifuge

For proper operation of a centrifuge, only those tubes recommended by their manufacturer should be used. The material used for the tube must withstand the RCF to which the tube is likely to be subjected. Polypropylene tubes generally are capable of withstanding RCFs of up to $5000 \times g$. The tubes should have a tapered bottom, particularly if a supernatant is to be removed, and should be of a size to fit securely into the rack to be centrifuged. The top of the tube should not protrude so far above the bucket that the swing into a horizontal position is impeded by the rotor.

For smooth operation of the centrifuge, the rotor must be properly balanced. The weight of racks, tubes, and their contents on opposite sides of a rotor should not differ by more than 1% or by an acceptable limit established by the manufacturer. Centrifuges that automatically balance their rotors are now available.

Tubes of collected blood should be centrifuged before they are unstoppered to reduce the probability of an aerosol being produced when the tube is opened. The practice of using a wooden applicator to release a clot stuck to the top of the tube or to its stopper should be avoided; it is a potential cause of hemolysis. Centrifugation at an appropriate RCF usually ensures that the clot is released from the tube wall and is drawn to the bottom of the tube.

Specific recommendations for each type of collection tube regarding RCF or times for centrifugation of blood specimens are usually provided by the manufacturer. Standards have not been established for centrifugation of other specimens, such as serum to which a protein precipitant has been added. Additional details pertaining to the handling and processing of blood specimens can be found in [Chapter 6](#) and CLSI document GP44-A4.

Operating Practice

Cleanliness of a centrifuge is important in minimizing the possible spread of infectious agents, such as hepatitis viruses. With proper operation of a centrifuge, fewer tubes will break. In case of breakage, the racks and chamber of the centrifuge must be carefully cleaned. Any spillage should be considered a possible bloodborne pathogen hazard. Gray dust arising from sandblasting of the chamber by fragments of glass indicates tube breakage and possible contamination, necessitating cleaning of the chamber. Broken glass embedded in cushions of tube holders may be a continuing cause of breakage if cushions are not inspected and replaced as part of the cleanup procedure.

The speed of a centrifuge should be checked according to the manufacturer's instructions or according to its intended use. The measured speed should not differ by more than 5% from the rated speed under specified conditions. All the speeds at which the centrifuge is commonly operated should be checked. The centrifuge timer should be checked weekly against a reference timer (such as a stopwatch), and the timer should not be more than 10% in error. Commutators and brushes should be checked depending on the frequency of use. Brushes (where used) should be replaced when they show considerable wear. However, in many modern induction-driven motors, brushes have been eliminated, thus removing a source of dust that causes motor failure.

Because centrifuges generate heat, the temperature in the chamber in many centrifuge models may increase by as much as 5°C after a single run. When the material to be centrifuged is thermolabile, a refrigerated centrifuge should be used. In the simplest form, a refrigerator unit is mounted beside the centrifuge, and cold air is blown into the rotor chamber. This approach is usually inadequate to stabilize the low temperature. In more sophisticated centrifuges, refrigeration coils around the chamber make it possible to maintain a preset temperature within $\pm 1^\circ\text{C}$. The temperature of a refrigerated centrifuge should be measured monthly under reproducible conditions and should be within 2°C of the expected temperature.

Gravimetry

Mass is an invariant property of matter. Gravimetry is the process used to measure the mass of a substance. Weight is a function of mass under the influence of gravity, a relationship expressed by the relationship

$$\text{Weight} = \text{Mass} \times \text{Gravity}$$

Two substances of equal weight and subject to the same gravitational force have equal mass. Mass is determined using a balance to compare the mass of an unknown with that of a known mass. This comparison is called weighing, and the absolute standards with which masses are compared are called weights. In practice, the terms mass and weight are used synonymously.

The classic form of a balance is a beam poised on an agate knife-edge fulcrum, with a pan hanging from each end of the beam and a rigid pointer hanging from the beam at the poised point. With the object to be weighed on one pan and weights of equal mass on the other pan, the pointer comes to rest at an equilibrium or balance point between the extremes of the path of excursion. The weight required to achieve the equilibrium is therefore equal to the weight of the substance being weighed.

Principles of Weighing

In practice, one of two modes of weighing is used: (1) analytical weights are added to equal the weight of the object being weighed, or (2) the material to be weighed is added to a balance pan to achieve equilibrium with a preset weight. This second

mode is used more commonly in clinical laboratories, where the major necessity is to weigh a fixed quantity of chemical so that a calibrator or reagent solution of known concentration may be prepared. Before a sample of the chemical is weighed, the weight of the container must be determined to subsequently allow for deducting the weight of the container from the gross weight of the container plus the sample to obtain the net weight of the sample. Most modern balances allow for the readout to be set to "0" with an empty container on the pan. This is called *taring*. When taring is impractical, the weight of the empty container must be subtracted from the combined weight of the container and the material to obtain the weight of the material alone.

Types of Balances

Double- and single-pan and electronic balances are frequently used in the clinical laboratory.

Double-pan balance. A double-pan balance conforms to the classic design, consisting of a single beam with arms of equal length. Standard weights are usually added by hand to one pan to counterbalance the weight of the object on the other; but in some models, a dial or vernier with a chain is used to make fine adjustments to the mass associated with the right-side pan. Double- and triple-beam balances are forms of the unequal-arm balance. These balances may be coupled directly to a computer or recording device.

Single-pan balance. The single-pan balance is a commonly used balance in the clinical laboratory. It is most often electronically operated and self-balancing. In single-pan balances, the arms are of unequal length. The object to be weighed is placed on the pan attached to the shorter arm. A restoring force is applied mechanically or electronically to the other arm to return the beam to its null position. In the electronic single-pan balance, a load on the pan causes the beam to tilt downward. A null detector senses the position of the beam and indicates when the beam has deviated from the equilibrium point.

Electronic balance. An electronic balance, as mentioned previously, uses an electromagnetic force to return the balance beam to its null position. This force is proportional to the weight on the pan. Most electronic balances have a built-in provision for taring so that the mass of the container is subtracted easily from the total mass measured. In addition, in many modern balances, a built-in computer compensates for changes in temperature and provides both automatic zero tracking and calibration.

Analytical Weights

Analytical weights are used to counterbalance the weight of objects weighed on two-pan balances and to verify the performance of both single- and two-pan balances. The NIST recognizes five classes of analytical weights. Class S weights are used for calibrating balances. In the clinical laboratory, balances should be calibrated at least monthly and before very accurate analytical work is conducted. These weights are typically made from brass or stainless steel, and are lacquered

or plated for protection. The fractional weights of a set of class S standards are usually made of platinum or aluminum. Tolerances of the different weights have been defined by the NIST. For class S weights from 1 to 5 g, the tolerance is ± 0.054 mg; from 100 to 500 mg, it is ± 0.025 mg; and from 1 to 50 mg, it is ± 0.014 mg.

Thermometry

In the clinical chemistry laboratory, measurements of temperature are made primarily to verify that devices measure within their prescribed temperature limits. Water baths and heated cells where reactions take place are examples of such devices, as are refrigerators, whose temperatures must be measured and recorded daily to meet laboratory regulatory requirements.

The two most popular types of thermometers in the chemistry laboratory are liquid-in-glass thermometers and thermistor probes.

All thermometers must be verified against a certified thermometer before they are placed into use. For example, the NIST SRM 934 is a mercury-in-glass thermometer with calibration points at 0°C , 25°C , 30°C , and 37°C . Some manufacturers supply liquid-in-glass thermometers that have ranges greater than the SRM thermometer and are verified to have been calibrated against the NIST thermometers. Details of verification of the calibration of a thermometer have been described. The NIST also supplies several materials that melt at a known temperature, including gallium (SRM 1968), which melts at 29.7723°C , and rubidium (SRM 1969), which melts at 39.3°C .

Procedures for Processing Solutions

Several procedures are used routinely to process solutions in the clinical laboratory, including those used for diluting, concentrating, and filtering solutions.

Dilution

Dilution is the process by which the concentration or activity of a given solution is decreased by the addition of a solvent. In laboratory practice, most dilutions are made by transferring an exact volume of a concentrated solution into an appropriate flask and then adding water or other diluent to the required volume, with appropriate mixing to ensure homogeneity. A serial dilution is a sequential set of dilutions in mathematical sequence. A given dilution is expressed as the amount, either volume or weight, of a solute (**analyte**) in a specified volume. For example, a 1:5 volume-to-volume dilution contains one volume of an initial solution in a total of five volumes of final solution (one volume plus four volumes). The dilution factor for a diluted solution is the reciprocal of the dilution of the initial solution. The dilution ratio is typically the ratio of the parts of volume (V_1) to the parts of another volume (V_2) or 1:4 in the previous example.

To prevent errors that arise when two liquids of different composition are mixed, the technique of diluting to volume is used. Instead of adding 90 mL of water to 10 mL of concentrated solution, the 10 mL of concentrated solution should be

pipetted into a 100-mL volumetric flask. Water is added to bring the volume to the 100-mL mark on the neck of the flask.

When a dilution is performed, the following equation is used to determine the final volume (V_2) necessary to dilute a given volume (V_1) of solution of a known concentration (C_1) to the desired lesser concentration (C_2):

$$C_1 \times V_1 = C_2 \times V_2 \quad (8.1)$$

or

$$V_2 = \frac{C_1 \times V_1}{C_2} \quad (8.2)$$

Likewise, Eq. 8.1 is also used to calculate the concentration of the diluted solution when a given volume is added to the starting solution.

Evaporation

Evaporation is a process used to convert a liquid or a volatile solid into vapor. It is used in the clinical laboratory to remove liquid from a sample, thereby increasing the concentrations of analyte(s) left behind. A centrifugal evaporator is used to gently evaporate solvents from single or multiple samples. The components include a centrifuge, a vacuum pump, and a cold trap to collect evaporated solvent. A centrifugal force is applied to create a pressure gradient so samples boil from the top down to prevent “bumping.” As the solvent is removed, the samples increase in concentration. The evaporation of solvent can also be accomplished by gently blowing a steady stream of gas, typically with its flow regulated through a needle, over the solution. Dry nitrogen gas is commonly used because it is relatively nonreactive.

Lyophilization

Lyophilization (also known as *freeze drying*) is used in laboratory medicine for the preparation of (1) calibrators, (2) control materials, (3) reagents, and (4) individual specimens for analysis. Lyophilization entails first freezing a material at -40°C or less and then subjecting it to a high vacuum. Very low temperatures cause the ice to sublime to a vapor state. The solid nonsublimable material remains behind in a dried state.

Filtration

Filtration is defined as the passage of a liquid through a filter and is accomplished by gravity, pressure, or vacuum. Filtrate is the liquid that has passed through the filter, and the fraction that does not pass through the filter is the retentate. The purpose of filtration is to remove particulate matter from the liquid. Many filtrations in the clinical laboratory are carried out with filter paper and with plastic membranes of controlled pore size.

Membrane filters are used (1) under vacuum, (2) with positive pressure, or (3) with gravity. Filters have been incorporated into certain disposable tips for use with semi-automatic pipettes. These filters minimize the exchange of aerosol droplets between the tips and the pipette. This is of particular importance for DNA amplification and microbiological procedures. Other membrane filters are designed for

ultrafiltration and are available with a variety of pore sizes for selective filtration. Ultrafiltration is a technique for removing dissolved particles using an extremely fine filter. It is used to concentrate macromolecules, such as proteins, because smaller dissolved molecules pass through the filter.

SAFETY

In the United States, the Federal Occupational Safety and Health Act of 1970 marked the beginning of formal regulatory oversight of employee safety. Since 1970, the **Occupational Safety and Health Administration (OSHA)** and the Centers for Disease Control and Prevention (CDC) have published numerous safety standards that apply to clinical laboratories. Each year, as The Joint Commission (JC) and CAP revise their guidelines, more attention is devoted to safety. Consideration for the health as well as responsibility for the safety of employees are now accepted as obligations of all employers and laboratory directors. In May 1988, OSHA expanded the Hazard Communication Standard to apply to hospital workers. Part of this standard is frequently referred to as the “Lab Right to Know Standard.”

Outside of the United States, the regulations and practices regarding laboratory safety and quality are guided by ISO 15189:2012 Medical laboratories: Requirements for quality and competence. This comprehensive international standard provides guidance on management, staffing, customers, laboratory, quality control, and quality improvement.

There are many aspects to the safe operation of a clinical laboratory. Key elements for safety in the clinical laboratory include:

1. A formal safety program.
2. Documented policies and effective use of mandated plans and/or programs in the areas of chemical hygiene, control of exposure to bloodborne pathogens, TB control, and **ergonomics**.
3. Identification of significant occupational hazards, such as biological, chemical, fire, and electrical hazards, and clear identification and documentation of policies for employees to deal with each type of hazard (e.g., packaging and shipping of diagnostic specimens and infectious substances).
4. Recognition that there are additional important and relevant safety areas of concern. These areas include effective waste management and bioterrorism and chemical terrorism response plans in the event of potential threats or casualties involving these types of agents.

Safety Program

Every clinical laboratory must have and implement a comprehensive formal safety program. Regardless of the size of the clinical laboratory, a specific individual should be designated as the “Safety Officer” or “Chair of the Safety Committee” and given the responsibility to implement and maintain a safety program. Safety is each employee’s responsibility, but responsibility for the entire program begins with the laboratory leadership (directors, administrative directors, supervisors,

managers, and so on) and is delegated through the leadership to the safety officer or safety committee. This individual or committee then has the duties of providing guidance to laboratory leadership on matters related to the provision of a safe workplace for all employees. Although a small institution may have one individual who deals with all safety-related matters for all departments, including the laboratory, OSHA mandates that the laboratory specifically have a chemical hygiene officer, who is designated on the basis of training or experience to provide technical guidance in the development of the **chemical hygiene plan (CHP)**, which is discussed later.

An integral part of the laboratory safety program is the education and motivation of all laboratory employees in all matters related to safety. All new employees should be given a copy of the general laboratory safety manual as part of their orientation. The continuing education program of the laboratory should include periodic talks on safety. Safety information is available from a variety of sources to support the continuing education element of the safety program.

Another important part of the laboratory safety program relates to ensuring that the laboratory environment meets accepted safety standards. This would include, but would not be limited to, attention to such items as (1) proper labeling of chemicals, (2) types and locations of fire extinguishers, (3) hoods that are in good working order, (4) proper grounding of electrical equipment, (5) ergonomic issues (which include equipment, such as pipetting devices, laboratory furniture, and prevention of musculoskeletal disorders), and (6) providing means for the proper handling and disposal of biohazardous materials, including all patient specimens.

Safety Equipment

OSHA requires that institutions provide employees with all necessary personal protective equipment (PPE). Key important safety items are (1) clothing (such as laboratory coats, gowns, and/or scrubs), (2) gloves, and (3) eye protection. These safety items should be used in areas where they are appropriate. Eye washers or face washers should be available in every chemistry laboratory. Many types are available, and some simply connect to existing plumbing. A handheld eye and/or face safety spray is a requisite safety device and is typically placed in a position next to each sink using only a few inches of space. Safety showers, strategically located in the laboratory, must be available and should be tested on a regular schedule.

Heat-resistant (nonasbestos) gloves should be available for handling hot glassware and dry ice. Safety goggles, glasses, and visors, including some that fit conveniently over regular eyeglasses, are available in many sizes and shapes. Personnel wearing contact lenses should be aware of the danger of irritants getting under a lens, making it difficult to irrigate the eye properly. Shatterproof safety shields should be used in front of systems posing a potential danger because of implosion (vacuum collapse) or pressure explosions. Desiccator guards should be used with vacuum desiccators. Hot beakers should be handled with tongs. Inexpensive polyethylene pumps are available to pump acids

from large bottles. Spill kits for acids, caustic materials, or flammable solvents come in various sizes. Such kits and the other appropriate safety materials should be located in convenient and appropriate sites in the laboratory.

A chemical fume hood is a necessity for every clinical chemistry laboratory. In practice, it is used for (1) opening any container of a material that gives off harmful vapors, (2) preparing reagents that produce fumes, and (3) heating flammable solvents. In the event of an explosion or a fire in the hood, closing its window contains the fire.

Safety Inspections

It is good laboratory practice to organize a safety inspection team from the laboratory staff. This team is responsible for conducting periodic and scheduled safety inspections of the laboratory.

In the United States, several regulatory, private accreditation, state, and federal organizations may conduct a safety inspection of the laboratory. Some of these safety inspections may occur unannounced. From an external perspective, OSHA inspectors have the authority to enter a clinical laboratory unannounced, and on presentation of credentials, inspect it. The inspection may be regular or may occur as the result of a complaint or an accident in the lab. In addition, the Commission on Inspection and Accreditation of CAP inspects clinical laboratories and uses various safety checklists (available to the laboratory before inspection) when evaluating a laboratory for accreditation. Although the JC will accept CAP accreditation of a laboratory, it still may conduct a safety inspection of the laboratory when it inspects the hospital. The CAP and JC conduct their accreditation inspections, which may include a full laboratory or laboratory safety component, unannounced.

Depending on the group designated as responsible for accrediting a particular laboratory, selected laboratories may be subject to inspections for the purposes of accreditation and/or safety only by state agencies or local Centers for Medicare and Medicaid Services (CMS) groups. Inspections may be made on a regular basis by state or local health departments or by local fire departments to determine compliance with their particular safety requirements. Currently, a laboratory that meets federal or state OSHA requirements is likely to satisfy the standards of any other inspecting agency.

Plans for the Clinical Laboratory

In 1991, OSHA mandated that all clinical laboratories in the United States must have a CHP and an **exposure control plan**. OSHA has since updated their requirements for the exposure control plan to provide new examples of engineering controls and to place significantly greater responsibility on employers to minimize and manage employee occupational exposure to bloodborne pathogens. The CAP and other groups require that an accredited laboratory must have a documented TB exposure control plan that conforms to biosafety guidelines published by the CDC. Elements of the plan must include regularly defined intervals for employee exposure, as well as

process controls, to minimize exposure to aerosolization of *Mycobacterium tuberculosis*.

In addition, it is now recognized that the workplace setting of a clinical laboratory exposes employees to the occupational risk of developing various musculoskeletal disorders. As a result, the focus of OSHA on laboratories that have an effective ergonomics program has led to federal, state, and private accreditation groups addressing this area of occupational safety. However, considerable controversy on this issue is ongoing, with a final ergonomics rule published and then withdrawn in 2001.

Chemical Hygiene Plan

Major elements of a CHP include listing of responsibilities for employers, employees, and a chemical hygiene officer. Also, every laboratory must have a complete chemical inventory that is updated annually. A copy of the **Material Safety Data Sheet (MSDS)**, which defines each chemical as toxic, carcinogenic, or dangerous, must be on file, readily accessible, and available to all employees 24 hours a day, 7 days a week. The MSDS contains important information for the benefit of laboratory employees. The chemical manufacturer's information, as supplied on the MSDS, is used to ascertain whether a certain chemical is hazardous. Each MSDS must give the product's identity as it appears on the container label and the chemical and common names of its hazardous components. The MSDS also provides physical data on the product, such as boiling point, vapor pressure, and specific gravity. Easily recognized characteristics of the chemical are also listed on the line for "appearance and odor." Information about hazardous properties is given in detail on the MSDS; this includes fire and explosion hazard data and health-related data such as the threshold limit value, exposure limits, and toxicity values. The threshold limit value is the exposure allowable for an employee during one 8-hour day. It also notes effects of overexposure and details first-aid procedures. Each MSDS also provides information on spill cleanup and disposal procedures, and protective personal gear and equipment requirements.

Exposure Control Plan

OSHA regulations require that each laboratory develop, implement, adhere to, and maintain a plan that ensures the protection of laboratory workers against potential exposure to bloodborne pathogens, and that medical wastes produced by the laboratory are managed and handled in a safe and effective manner. OSHA regulations also place responsibility on employers to implement new developments in exposure control technology, to solicit the input of employees directly involved in patient care in the identification, evaluation, and selection of these work practice controls, and in certain instances to maintain a log for employee percutaneous injuries from sharp devices such as syringe needles. Organizationally, the plan should include sections on (1) purpose, (2) scope, (3) applicable references, (4) applicable definitions, (5) definition of responsibilities, and (6) detailed procedural steps.

When implementing the plan, each laboratory employee must be placed into one of the following three groups:

Group I: a job classification in which all employees have occupational exposure to blood or other potentially infectious materials.

Group II: a job classification in which some employees have occupational exposure to blood or other potentially infectious materials.

Group III: a job classification in which employees do not have any occupational exposure to blood or other potentially infectious materials.

Tuberculosis Control Plan

The purpose of the TB control plan is to prevent the transmission of TB, which occurs when an individual inhales a droplet that contains *M. tuberculosis*. *M. tuberculosis* is aerosolized when an infected individual sneezes, speaks, or coughs, or when an infected sputum specimen is handled (http://www.cdc.gov/tb/publications/guidelines/control_elim.htm). Transmission of and exposure to TB are greatly diminished with (1) early identification and isolation of patients at risk, (2) environmental controls, (3) appropriate use of respiratory protection equipment, (4) education of laboratory employees, and (5) early initiation of therapy.

An effective TB control plan will include determination of exposure at regular intervals for all employees who are at occupational risk. Engineering and work practice controls are particularly important in laboratory areas, such as surgical pathology and microbiology. However, there is a clear risk of exposure from specimens of patients with suspected or confirmed TB in every section of the laboratory, including chemistry.

Pandemic Plan

A pandemic is an epidemic of infectious disease that spreads through populations across a large region or even worldwide. An influenza pandemic is a worldwide outbreak or epidemic caused by an influenza virus. For example, the influenza pandemic of 1918 to 1919 killed between 20 and 50 million people with more than 500,000 deaths reported in the United States alone (<http://www.cdc.gov/flu/about/qa/1918flupandemic.htm>).

Influenza viruses capable of causing a pandemic (1) must cause human disease, (2) have novel surface antigens, and (3) must be able to be spread effectively from person to person. Beginning in 1997, an outbreak of avian influenza (strain H5N1) affected birds in several countries in Asia, Africa, and Europe. This strain has been shown to cause lethal disease among humans and created concern that it might evolve into a strain of virus capable of causing a pandemic. Subsequently, many states in the United States developed pandemic influenza control or response plans.

A novel influenza A (H1N1) of swine origin was first detected in April 2009. This virus was found to be highly infectious, easily spreading from person to person, and led to an outbreak of illness in the United States and internationally

(<http://www.cdc.gov/h1n1flu>). A global pandemic was declared by the WHO in June 2009.

Because of the potential for exposure of individuals working in health care settings, the CDC has published recommendations for establishing infection control. These recommendations provide guidance for all individuals who may be processing or performing diagnostic testing on clinical specimens from patients with suspected novel influenza A (H1N1) virus infection, or performing viral isolation.

The Ebola virus, which first appeared in Central Africa in 1976, reappeared in West Africa in 2014. The Ebola virus causes an acute, serious illness that can lead to death when untreated. The virus is transmitted from animals to humans and can easily spread through human-to-human transmission. This highly contagious virus can easily become a pandemic situation if not controlled properly. Health care workers and laboratories need to be prepared for these types of infectious agents.

Ergonomics Program

Several areas of occupational risk for development of musculoskeletal disorders have been identified in the clinical laboratory. These include (1) routine laboratory activity, (2) functionality of the workspace (including laboratory floor matting, bright lighting, and noise generation), and (3) equipment design (computer keyboards and displays, workstations, and chairs). One particular laboratory function, pipetting and related pipette design, has received considerable attention. As depicted in Fig. 8.2, pipettes are being designed with the goal of reducing an employee's risk of developing cumulative stress disorders caused by awkward posture, repetitive motion, and repeated use of force.

The CAP requires accredited laboratories to have a comprehensive and defined ergonomics program that is designed to prevent work-related musculoskeletal disorders through prevention and engineering controls. The documented ergonomics plan should include elements of employee training regarding the areas of risk, engineering controls to minimize or eliminate risks, and an assessment process to identify problematic issues for documentation and remediation.

Hazards in the Laboratory

Various types of hazards are encountered in the operation of a clinical laboratory. These hazards must be identified and labeled, and work practices developed for dealing with them. The major categories of hazards encountered include (1) biological, (2) chemical, (3) electrical, and (4) fire hazards.

Identification of Hazards

Clinical laboratories deal with each of the nine classes of hazardous materials. These are classified by the United Nations (UN) as (1) explosives, (2) compressed gases, (3) flammable liquids, (4) flammable solids, (5) oxidizer materials, (6) toxic materials, (7) radioactive materials, (8) corrosive materials, and (9) miscellaneous materials not classified elsewhere. Shipping and handling of class 6 toxic materials, specifically

Fig. 8.5 (A) US Department of Transportation label for corrosives. (B) Labeling identification system of the National Fire Protection Association. (Courtesy Lab Safety Supply Inc., Janesville, WI.)

biological and potentially infectious materials, has received considerable attention. In 2002, the US Department of Transportation (DOT) released a revised rule with standards for infectious substance hazardous material handling. Warning labels aid in the identification of chemical hazards during shipment. Under regulations of the DOT, chemicals that are transported in the United States must carry labels based on the UN classification. DOT placards or labels are diamond shaped with a digit imprinted on the bottom corner that identifies the UN hazard class (1 to 9). The hazard is identified more specifically in printed words placed along the horizontal axis of the diamond. Color coding and a pictorial art description of the hazard supplement the identification of hazardous material on the label; the artwork appears in the top corner of the diamond (Fig. 8.5A).

The system is used by the DOT for shipping hazardous materials; however, when the hazardous material reaches its destination and is removed from the shipping container, this identification is lost. The laboratory must then label each individual container. Usually, the information necessary to

classify the contents of the container appropriately is on the shipping label and should be noted. Important first aid information is usually provided on this label.

Although OSHA at present prescribes the use of labels or other appropriate warnings, no single uniform labeling system for hazardous chemicals exists for use by clinical laboratories. Appropriate hazard warnings include any words, pictures, symbols, or combinations that convey the health or physical hazards of the container's contents and must be specific as to the effect of the chemical and the specific target organs involved. The National Fire Protection Association (NFPA) has developed the 704-M Identification System, which classifies hazardous material from 0 to 4 (most hazardous) according to flammability and reactivity (instability). This system uses diamond-shaped labels (see Fig. 8.5B), which are available from most companies that sell laboratory safety equipment. The labels are color coded and are divided into quadrants. Three of the quadrants have a characteristic color and represent a type of hazard. A number in the quadrant indicates the degree of hazard. The fourth (lower) quadrant contains information of special interest to firefighters.

Biological Hazards

It is essential to minimize the exposure of laboratory workers to infectious agents, such as the hepatitis viruses, HIV, and flu viruses. Exposure to infectious agents results from (1) accidental puncture with needles, (2) spraying of infectious materials by a syringe or spilling and splattering of these materials on bench tops or floors, (3) centrifuge accidents, and (4) cuts or scratches from contaminated vessels. Any unfixed tissue, including blood slides, must also be treated as potentially infectious material.

OSHA has mandated that all US laboratories have an exposure control plan. In addition, the National Institute for Occupational Safety and Health, a functional unit of the CDC, has prepared and widely distributed a document entitled **Standard Precautions** that specifies how US clinical laboratories should handle infectious agents. In general, it mandates that clinical laboratories treat all human blood and other potentially infectious materials as if they were known to contain infectious agents, such as hepatitis B virus (HBV), HIV, and other bloodborne pathogens. These requirements apply to all specimens of (1) blood, (2) serum, (3) plasma, (4) blood products, (5) vaginal secretions, (6) semen, (7) cerebrospinal fluid, (8) synovial fluid, and (9) concentrated HBV or HIV viruses. In addition, any specimen of any type that contains visible traces of blood should be handled using these Standard Precautions.

Standard Precautions also specify that barrier protection must be used by laboratory workers to prevent skin and mucous membrane contamination from specimens. These barriers, also known as PPE, include (1) gloves, (2) gowns, (3) laboratory coats, (4) face shields or mask and eye protection, (5) mouthpieces, (6) resuscitation bags, (7) pocket masks, and (8) other ventilator devices. A latex allergy is a problem for some individuals when latex gloves

are used for barrier protection. For such individuals, medical grade gloves made of materials such as vinyl, nitrile, neoprene, or thermoplastic elastomer are available. If latex gloves are to be used, they should be made of powder-free, low-allergen latex.

New products for increasing employee protection against needle sticks include an array of novel containers for sharps (e.g., needles, scalpels, glass) and biological safety disposal bags and needle sheaths that may be closed following venipuncture without physically touching the needle or the sheath. Although additional studies on their efficacy and effects on laboratory test results are required, microlaser devices are now available for piercing a patient's skin to collect a capillary blood specimen.

The CLSI has published a similar set of recommendations, several of which are specified as requirements in the OSHA exposure control plan. They include the following:

1. Never perform mouth pipetting and never blow out pipettes that contain potentially infectious material.
2. Do not mix potentially infectious material by bubbling air through the liquid.
3. Barrier protection, such as gloves, masks, and protective eyewear and gowns, must be available and used when drawing blood from a patient and when handling all patient specimens. This includes the removal of stoppers from tubes. Gloves must be disposable, nonsterile latex or of other material to provide adequate barrier protection. Phlebotomists must change gloves and adequately dispose of them between drawing blood from different patients.
4. Wash hands whenever gloves are changed.
5. Facial barrier protection should be used if there is a significant potential for the spattering of blood or body fluids.
6. Avoid using syringes whenever possible and dispose of needles in rigid containers (Fig. 8.6A) without handling them (see Fig. 8.6B).
7. Dispose of all sharps appropriately.
8. Wear protective clothing, which serves as an effective barrier against potentially infective materials. When leaving the laboratory, the protective clothing should be removed.
9. Strive to prevent accidental injuries.
10. Encourage frequent hand washing in the laboratory; employees must wash their hands whenever they leave the laboratory.
11. Make a habit of keeping your hands away from your mouth, nose, eyes, and any other mucous membranes. This reduces the possibility of self-inoculation.
12. Minimize spills and splatters.
13. Decontaminate all surfaces and reusable devices after use with appropriate US Environmental Protection Agency-registered hospital disinfectants. Sterilization, disinfection, and decontamination are discussed in detail in CLSI publication M29-A4.
14. No warning labels are to be used on patient specimens because all should be treated as potentially hazardous.

A

B

Fig. 8.6 (A) Convenient needle disposal system for sharps. (B) Needle sheathing devices for prevention of body contact with needle. ([B] Courtesy Marketlab Inc.)

15. Biosafety level 2 procedures should be used whenever appropriate.
16. Before centrifuging tubes, inspect them for cracks. Inspect the inside of the trunnion cup for signs of erosion or adhering matter. Be sure that rubber cushions are free from all bits of glass.
17. Use biohazard disposal techniques (e.g., "Red Bag").
18. Never leave a discarded tube or infected material unattended or unlabeled.
19. Periodically, clean out freezer and dry-ice chests to remove broken ampoules and tubes of biological specimens. Use rubber gloves and respiratory protection during this cleaning.
20. OSHA requires that hepatitis B vaccine be offered to all employees at risk of potential exposure as a regular or

occasional part of their duties. The Advisory Committee on Immunization Practices of the CDC recommends that medical technologists, phlebotomists, and pathologists be vaccinated with hepatitis B vaccine. It is a regulatory mandate that all of the previously mentioned laboratory employees at a minimum be given the option to receive free hepatitis B vaccine.

Investigation of tragic air accidents in the late 1990s by the US National Transportation Safety Board led to the development of revised and strict requirements for the shipping and handling of hazardous materials by DOT, in cooperation with the International Air Transport Association and the International Civil Aviation Organization.

These regulations place particular emphasis on the hazardous material training that must be given to laboratory employees regarding shipping and handling of infectious substances. Elements include general awareness and familiarization, function-specific information, and safety training. Proper training, particularly in the areas of package labeling and documentation (including a shipper's declaration of contents for dangerous goods), is mandatory, and documented certification from employers that the relevant employees have had appropriate training programs is required. Although the adverse impact of improper training can be reflected most by potential human morbidity and mortality, identified violations of these regulations also carry large financial fines and penalties for both the infringing individual and the employer or institution.

Chemical Hazards

Proper storage and use of chemicals is necessary to prevent dangers, such as burns, explosions, fires, and toxic fumes. Thus knowledge of the properties of the chemicals in use and of proper handling procedures greatly reduces dangerous situations. Bottles of chemicals and solutions should be handled carefully, and a cart should be used to transport heavy or multiple numbers of containers from one area to another. Glass containers with chemicals should be transported in rubber or plastic containers that protect them from breakage, and in the event of breakage, contain the spill. Appropriate spill kits should be available in strategic locations.

Spattering from acids, caustic materials, and strong oxidizing agents is a hazard to clothing and eyes and is a potential source of chemical burns. A bottle should never be held by its neck but instead firmly around its body with one or both hands, depending on the size of the bottle. Acids must be diluted by slowly adding them to water while mixing; water should never be added to concentrated acid. When working with acid or alkali solutions, safety glasses should be worn. Acids, caustic materials, and strong oxidizing agents should be mixed in the sink. This provides water for cooling and for confinement of the reagent in the event that the flask or bottle breaks.

All bottles containing reagents must be properly labeled. It is good practice to label the container before adding the reagent, thus preventing the possibility of having an unlabeled reagent. The label should bear the (1) name and

concentration of the reagent, (2) initials of the person who made up the reagent, and (3) the date on which the reagent was prepared. When appropriate, the expiration date should also be included. The labels should be color-coded or an additional label added to designate specific storage instructions, such as the requirement for refrigeration or special storage related to a potential hazard. All reagents found in unlabeled bottles should be disposed of using appropriate procedures and precautions.

Strong acids, caustic materials, and strong oxidizing agents should be dispensed by a commercially available automatic dispensing device. Under no circumstances is mouth pipetting permitted.

In some instances, all waste materials are not collected in the same container. With certain pieces of equipment, strong acids or other hazardous materials are pumped directly into the drain. This should always be accompanied by a steady flow of water from the faucet. Safety glasses should be used by instrument operators when acids are pumped under pressure.

Perchloric acid, because it is potentially explosive in contact with organic materials, requires careful handling. Perchloric acid should not be used on wooden bench tops, and bottles of this acid should be stored on a glass tray. Disposal may be accomplished by adding the acid dropwise (using a splatter shield) to at least 100 volumes of cold water and pouring the diluted acid down the drain with large amounts of additional cold water. Special perchloric acid hoods, with special wash-down facilities, should be installed if large amounts of this acid are used.

Special care is necessary when dealing with mercury. Even small drops of mercury on bench tops and floors may poison the atmosphere in a poorly ventilated room. The element's ability to amalgamate with a number of metals is well known. After an accidental spillage of mercury, the spill area should be cleaned carefully until no droplets are remaining. All containers of mercury should be kept well stoppered. Because it is highly hazardous, most recommend that no mercury be used in the laboratory.

The Environmental Protection Agency controls the disposal of nonradioactive hazardous wastes. The Resource Conservation and Recovery Act of 1976 states that disposal of materials classifiable within any of the nine UN hazardous materials classes is enforced in such a way that health and safety professionals involved in the disposal of such materials are personally liable for each individual violation.

A CLSI publication covers hazardous waste disposal; however, many municipalities and states have their own regulations. These agencies should be contacted by the laboratory for specifics. Volatile chemicals and compressed gases pose specific hazards.

Hazards from volatiles. The use of organic solvents in a clinical laboratory represents a potential fire hazard and hazards to health from inhalation of toxic vapors or skin contact. These solvents should be used in a fume hood. Storage of organic solvents is regulated by rules set down by OSHA. However, some local fire department rules are more stringent. Solvents should be stored in an OSHA-approved metal storage

cabinet that is properly vented. The maximum working volume of flammable solvents allowed outside storage cabinets is 5 gallons per room. No more than 60 gallons of type I and II solvents may be stored in a single cabinet. No more than three cabinets may be located in each 5000 sq ft of laboratory space.

Vaporization is a major problem in the ignition and spread of fires. Vapors from flammable and combustible liquids and solids form a flammable mixture with air. They are characterized by their flash point, where the flash point is defined as the lowest temperature at which a solvent gives off flammable vapors in the close vicinity of its surface. The mixture at its flash point ignites when exposed to a source of ignition. At temperatures below the flash point, the vapor given off is considered too lean for ignition.

Disposal of flammable solvents in storm sewers or sanitary sewers generally is not allowed. Exceptions are small amounts of those materials that are miscible with water, but even disposal of these should be followed by large amounts of cold water. Other solvents should be collected in safety cans. Separate cans should be used for ether and for chlorinated solvents; all other solvents may be combined in a third can. The cans should be stored, in keeping with storage quantity rules, in a safety cabinet until pickup by a waste disposal firm. A more economical approach is to transfer the solvents to larger cans or drums in an outside storage facility, so that pickup can be less frequent. Some large institutions have their own in-house disposal facilities.

Hazards from compressed gases. DOT regulations cover the labeling of cylinders of compressed gases that are transported by interstate carriers. The diamond-shaped labels described previously are used on all large cylinders and on any boxes containing small cylinders. Some general rules for handling large cylinders of compressed gas are as follows:

1. Always transport cylinders using a hand truck to which the cylinder is secured.
2. Leave the valve cap on a cylinder until the cylinder is ready for use, at which time the cylinder should have been secured by a support around the upper one third of its body. Disconnect the hose or regulator, shut off the valve, and replace the cap before the cylinder is completely empty to prevent the possibility of development of a negative pressure. Place an "empty" sign or label on the cylinder.
3. Chain or secure cylinders at all times even when empty.
4. Always check cylinders for the composition of their contents before connection.
5. Never force threads; if a regulator does not thread readily, something is wrong.

The precautions cited for large, refillable gas cylinders also apply to small cylinders that are not refillable. Propane cylinders and cylinders of calibrating gases for blood gas equipment are examples of disposable cylinders. Cylinders in floor-standing base supports require the additional security of a chain or strap attached to a wall or fixed piece of furniture. Local fire department regulations (which vary considerably from place to place) govern the disposal of exhausted cylinders.

Electrical Hazards

Electrical wires or connections are potential shock or fire hazards. Worn wires on all electrical equipment should be replaced immediately, and all equipment should be grounded using three-prong plugs. OSHA regulations stipulate that the requirements for grounding of electrical equipment of the National Electrical Code (published by NFPA) be met. If grounded receptacles are not available, a licensed electrician should be consulted for proper alternative grounding techniques. Some local codes are more stringent than OSHA requirements and do not allow for two-pole mating receptacles with adapters for a three-pole plug.

Use of extension cords is prohibited. This standard is more stringent than any other existing regulation. In some instances, an extension cord may have to be used temporarily. In such cases, the cord should (1) be less than 12 ft in length, (2) include at least 16 American Wire Gauge wire, (3) be approved by the Underwriters Laboratory, and (4) have only one outlet at the end. If several outlets are necessary in a single area, a power strip with its own fuse or circuit breaker may be installed at least 3 in above bench top level. Several manufacturers now sell devices to check for high resistance in neutral or ground wiring or excess voltage in neutral wiring.

Electrical equipment and connections should not be handled with wet hands, nor should electrical equipment be used after liquid has been spilled on it. The equipment must be turned off immediately and dried thoroughly. In case of a wet or malfunctioning electrical instrument that is used by several people, the plug should be pulled and a note cautioning coworkers against use should be left on the instrument.

Fire Hazards

NFPA and OSHA publish standards covering subjects from emergency exits (including means of egress) to safety and firefighting equipment. NFPA also publishes the National Fire Codes. Many state and local agencies have adopted these codes (some of which are more stringent than OSHA requirements), thus making them legally enforceable.

Every laboratory should have the necessary equipment to extinguish or confine a fire in the laboratory and to extinguish a fire on the clothing of an individual. Easy access to safety showers is essential. A safety shower should have a pull chain attached to the wall at a convenient height or hanging down from the shower head; the chain should have a large ring attached so that the shower may be easily activated, even with eyes closed. Fire blankets for smothering fire on clothing should be available in an easily accessible wall-mounted case. The blanket is unrolled from the case and is rolled around the body by taking hold of the rope that is attached to the blanket and turning the body around. The location of this equipment and the locations of fire alarms and maps of evacuation routes are dictated by the local fire marshal.

Various types of fire extinguishers are available. The type to use depends on the type of fire. Because it is impractical to

TABLE 8.2 Classification of Fires and Fire Extinguisher Requirements

Type of Hazard	Class of Fire	Recommended Extinguisher Agents
Ordinary combustibles: wood, cloth, paper	A	Water, dry chemical foam, loaded steam
Flammable liquids and gases: solvents and greases, natural or manufactured gases	B	Dry chemical, carbon dioxide, loaded steam, Halon 1211 or 1301 foam
Electrical equipment: any energized electrical equipment; if electricity is turned off at source, this reverts to a class A or B	C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles and flammable liquids and gases	A and B	Dry chemical, loaded steam, foam
Combinations of ordinary combustibles and electrical equipment	A and C	Dry chemical
Combinations of flammable liquids and gases and electrical equipment	B and C	Dry chemical, carbon dioxide, Halon 1211 or 1301 foam
Combinations of ordinary combustibles, flammable liquids and gases, and electrical equipment	A, B, and C	Triplex dry chemical

have several types of fire extinguishers present in every area, dry chemical fire extinguishers are among the best all-purpose extinguishers for laboratory areas. An extinguisher should be provided near every laboratory door, and in a large laboratory, at the end of the room opposite the door. Everyone in the laboratory should be instructed in the use of these extinguishers and any other available firefighting equipment. All fire extinguishers should be tested by qualified personnel at intervals specified by the manufacturer. The three classes of fires and the type of fire extinguisher to be used for each are listed in Table 8.2. Every fire extinguisher is labeled as to the type of fire it should be used to extinguish.

Two additional types of fires, designated “D” and “E,” should be handled only by trained personnel. Type D fires include those involving powdered metal materials (e.g., magnesium). A special powder is used to fight this hazard. A type E fire is one that cannot be put out or is liable to result in a detonation (such as an arsenal fire). A type E fire is usually allowed to burn out while nearby materials are appropriately protected.

Many clinical laboratories now have a computer that is housed in a temperature- and humidity-controlled room. The most popular automatic fire control system used for these rooms is Halon 1301 (bromotrifluoromethane). Although this is the least toxic of the halons, NFPA regulations require a warning sign at the entrance to the room and availability of self-contained breathing equipment.

POINTS TO REMEMBER

Safety Elements

Safety in the clinical laboratory contains many elements, including:

- A formal safety program
- A CHP
- A plan for exposure to bloodborne pathogens
- A plan for TB control
- An ergonomics plan
- Identification of significant occupational hazards
- A waste management plan
- A biochemical and chemical terrorism response plan

REVIEW QUESTIONS

- One aspect of Standard Precautions, and an Occupational Safety and Health Administration (OSHA) requirement, involves the provision of personal protective equipment (PPE) to laboratory employees. PPE includes (but is not limited to) which of the following?
 - Gloves only
 - Gloves and a lab coat only
 - Gloves, eye protection, and a lab coat
 - Gloves, eye protection, a lab coat, and special footwear
- Which of the following uses for analytical weights is false?
 - Analytical weights are used for verifying performance of single pan balances.
 - Class S weights are used for calibrating balances.
 - Balances must be calibrated each day of use for accurate analytical work.
 - Weights can be made of materials such as brass and platinum.
- The organization that develops and implements standards and guidelines for laboratories in addition to setting certain safety guidelines is:
 - CAP.
 - CLSI.
 - EPA.
 - DOT.
- The process by which the concentration or activity of a given solution is decreased by the addition of solvent is referred to as:
 - solution.
 - evaporation.
 - lyophilization.
 - dilution.
- The formula used to determine the molarity of a solution is which of the following?
 - $C_1 V_1 = C_2 V_2$
 - number of moles of solute/number of liters of solution

- c. mg/L divided by mg molecular mass
- d. mass in grams/gram molecular weight in grams
6. Which type of highly purified material needs to minimally be 99.98% pure?
 - a. Certified Reference Material
 - b. Standard Reference Material
 - c. Secondary Reference Material
 - d. Primary Reference Material
7. Which of the following statements regarding water purification is *incorrect*?
 - a. Water treated by distillation alone does not meet the specific conductivity requirement for Clinical Laboratory Reagent Water (CLRW).
 - b. Reverse osmosis forces water through a semipermeable membrane.
 - c. Only one purification process is necessary for obtaining CLRW.
 - d. UV oxidation can eliminate many bacteria and cleave ionizing organics.
8. The two chemical grades that are suitable for use in a clinical chemistry laboratory are:
 - a. technical and analytical reagent grades.
 - b. ultrapure and technical grades.
 - c. technical and National Formulary grades.
 - d. ultrapure and analytical reagent grades.
9. Relative centrifugal force or field (RCF) is measured in which of the following units?
 - a. Gravities (g)
 - b. Centimeters (cm)
 - c. rpm
 - d. Forces (f)
10. Protection of laboratory workers against potential exposure to bloodborne pathogens and assurance that medical waste is handled safely are OSHA requirements that are part of which of the following plans?
 - a. Chemical hygiene plan
 - b. Exposure control plan
 - c. Tuberculosis control plan
 - d. Fire safety plan

Optical Techniques

*Larry J. Kricka, Jason Y. Park**

OBJECTIVES

1. Define the following terms:
 - Absorbance
 - Atomic absorption (AA)
 - Beer's law
 - Electromagnetic radiation
 - Flame emission spectrophotometry
 - Fluorescence
 - Fluorescence polarization
 - Light
 - Nephelometry
 - Percent transmittance
 - Photometry
 - Spectral/natural bandwidth
 - Spectrophotometry
 - Stokes shift
 - Transmittance
 - Turbidimetry
 - Visible/ultraviolet/infrared spectrum
 - Wavelength
2. Describe the relationship between the light transmitted and the light absorbed by a solution of a compound; state this relationship as a mathematical formula.
3. Express Beer's law mathematically, and define each of the components of the formula; calculate the concentration of a substance in solution using Beer's law.
4. Explain how Beer's law is used to create a calibration curve, and list five conditions that must be met before Beer's law can be applied to a measurement.
5. List the basic components of generic single-beam and double-beam spectrophotometers and state the purpose of each of the components; provide and describe two examples, if appropriate, of each component.
6. State the principle of reflectance photometry and the clinical laboratory applications of this technique.
7. State the principle of AA spectrophotometry; list the clinical laboratory applications of this technique.
8. List the components of an AA spectrophotometer and the role each component plays in measurement.
9. Describe and give examples of spectral and nonspectral interferences that might limit measurements made using AA.
10. State the principle of fluorescence; list the clinical laboratory applications of this technique.
11. Express as an equation the derivation of the Beer-Lambert law in relation to fluorescence intensity and concentration, and define each of the components of this equation.
12. Compare the sensitivity of fluorescence intensity measurements with that of absorbance measurements, and list three reasons why fluorescence measurements are more sensitive.
13. Describe fluorescence polarization and its use in the clinical laboratory.
14. List the components of a generic fluorometer; list and describe four types of fluorometers, including their use in the clinical laboratory.
15. List and describe six possible interferences that influence fluorescence measurements.
16. Explain the basic concepts of chemiluminescence and electrochemiluminescence; list the clinical laboratory applications of these techniques.
17. Explain the basic concepts of light scattering, including six factors that affect light scattering.
18. Compare nephelometry and turbidimetry, and list the clinical laboratory applications of these techniques; describe a turbidimeter and a nephelometer.
19. List and describe two possible interferences that might limit light-scattering measurements.

*The authors gratefully acknowledge the original contributions by Dr. Merle A. Evenson and Dr. Thomas O. Tiffany, upon which portions of this chapter are based.

KEY WORDS AND DEFINITIONS

Absorbance (A) The amount of light absorbed as incident light passes through a sample, which is equivalent to $\log (1/T)$, where T is transmittance. Absorbance and transmittance are inverse properties. For example, when absorbance is low (0.0), the transmittance is high (100%) [$A = \log (1/1.00)$]. Conversely, when transmittance is low (10%), the absorbance is 1.0 [$A = 1.0 = \log (1/.10)$].

Absorptivity (a) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 g/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in g/L and the sample path length in centimeters ($a = A/bc$).

Atomic absorption spectrophotometry A technique in which an element in a sample is dissociated from its chemical bonds (atomized) and placed in an unexcited or ground state (neutral atom); the atom in the ground state is able to absorb radiation and the decrease in radiant energy from the light source transmitted through the sample is measured.

Bandpass The range of wavelengths passed by a filter or a monochromator at one-half the peak transmittance of that filter.

Beer's law A mathematical equation stating that the concentration of a substance is directly proportional to the amount of light absorbed, mathematically expressed as $A = abc$ or $A = \epsilon bc$.

Blank A solution used in photometry/spectrophotometry that is identical to the unknown solution except for the substance to be measured.

Chemiluminescence The emission of light when a molecule returns from an excited or higher energy level to a lower energy level, in which the excitation event is caused by a chemical reaction and not by photo illumination, for example, by the oxidation of an organic compound.

Electrochemiluminescence The emission of light when a molecule returns from an excited or higher energy level to a lower energy level, in which the excitation event is a reaction generated electrochemically on the surface of an electrode.

Flow cytometry The measurement of optical properties of cells or particles made while they pass singly through a measuring apparatus in a flowing fluid stream.

Fluorescence The emission of electromagnetic radiation that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength.

Fluorometry The measurement of emitted fluorescence light that occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength.

Light The energy transmitted via electromagnetic waves that are characterized by frequency and wavelength; light is composed of photons whose energy is inversely proportional to the wavelength.

Light scattering The redirection of light that results from the interaction of light with molecules or particles in solution without absorption taking place.

Molar absorptivity (ϵ) A proportionality constant for a compound that is the measure of the absorption of radiant energy at a given wavelength as it passes through a solution of that compound at a concentration of 1 mol/L; expressed mathematically as absorbance divided by the product of the concentration of a substance in mol/L and the sample path length in centimeters ($\epsilon = A/bc$).

Nephelometry The detection and measurement of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light; nephelometers may measure scattered light at right angles to the incident light, or at some angle other than 90 degrees.

Photometry/spectrophotometry The measurement of the luminous intensity of light or the amount of luminous light falling on a surface of a detector; spectrophotometry is the measurement of the intensity of light at varied wavelengths.

Reflectance photometry A spectrophotometric technique in which diffused light illuminates a reaction mixture in a carrier containing a substance of interest, and the intensity of the reflected light is measured and compared with a reference.

Spectral bandwidth The width in nanometers of the spectral transmittance curve at a point equal to one-half of the peak transmittance; used to describe the spectral purity of a filter or other monochromator.

Transmittance The intensity of a light beam that passes through a square cell containing a solution of a compound that absorbs light at a specific wavelength, divided by the intensity of an incident (incoming) light beam, stated as $T = I/I_0$.

Turbidimetry The detection and measurement of a decrease in intensity of an incident beam of light after it passes through a solution of molecules or particles.

Wavelength A characteristic of electromagnetic radiation; the distance between two adjacent maxima in a wave that is measured in nanometers.

Many determinations made in the clinical laboratory are based on measurements of radiant energy (1) emitted, (2) transmitted, (3) absorbed, (4) scattered, or (5) reflected under controlled conditions (Table 9.1). The basic principles involved in such measurements are described in this chapter.

PHOTOMETRY AND SPECTROPHOTOMETRY

Photometry is the measurement of the luminous intensity of a light source or the amount of luminous light falling on a surface from such a source. **Spectrophotometry** is the measurement of the intensity of light at selected wavelengths. Photometric

TABLE 9.1 Scope of Optical Methods

Type	Example
Absorption	Atomic absorption, densitometry, Fourier transform infrared spectroscopy, photometry, spectrophotometry, reflectance photometry, x-ray spectroscopy
Emission	Fluorescence correlation spectroscopy, fluorescence energy transfer spectroscopy, fluorometry, luminometry (light emission from a bioluminescent, chemiluminescent, or electrochemiluminescent reaction), phosphorimetry, time-resolved fluorometry
Polarization	Fluorescence polarization spectroscopy, polarimetry
Scattering	Nephelometry, turbidimetry

measurement was defined originally as the process used to measure light intensity independent of wavelength. However, modern instruments isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as filter photometers, whereas those that use prisms or gratings are called *spectrophotometers*. The primary analytical utility of filter photometry or spectrophotometry is the isolation and use of discrete portions of the spectrum for purposes of measurement.

Basic Concepts

Energy is transmitted via electromagnetic waves that are characterized by their frequency and **wavelength**. Analytically, the term wavelength describes a position within a spectrum. Electromagnetic radiation includes radiant energy that extends from cosmic rays with wavelengths as short as 10 nm up to radio waves longer than 1000 km. However, in this chapter, the term **light** is used to describe radiant energy from the ultraviolet (UV) to the visible light portions of the spectrum (290 to 750 nm).

In addition to possessing wavelength characteristics, light behaves as if it is composed of discrete energy packets called *photons*, whose energy is inversely proportional to the wavelength. For example, UV radiation at 200 nm possesses greater energy than infrared (IR) radiation at 750 nm.

Table 9.2 shows the approximate relationship between wavelengths and color characteristics for the UV, visible, and IR portions of the spectrum.

POINTS TO REMEMBER

Radiant Energy

- Wide distribution in wavelength size, ranging from as small as 10 nm to greater than 1000 km
- The visible portion of the spectrum ranges from ~380 to ~750 nm
- The energy of light is inversely proportional to the wavelength; shorter wavelengths have greater energy
- Light possesses both wavelength and energy packet characteristics; the packets are described as photons

TABLE 9.2 Ultraviolet, Visible, and Short Infrared Spectrum Characteristics Colors

Wavelength, nm	Region Name	Observed ^a
<380	Ultraviolet ^b	Invisible
380–440	Visible	Violet
440–500	Visible	Blue
500–580	Visible	Green
580–600	Visible	Yellow
600–620	Visible	Orange
620–750	Visible	Red
750–2,500	Near-infrared	Not visible
2,500–15,000	Mid-infrared	Not visible
15,000–1,000,000	Far-infrared	Not visible

^aOwing to the subjective nature of color, the wavelength intervals shown are only approximations.

^bThe ultraviolet (UV) portion of the spectrum is sometimes further divided into “near” UV (220 to 380 nm) and “far” UV (<220 nm). This arbitrary distinction has a practical basis because cuvetts made from silica transmit light effectively at wavelengths ≥ 220 nm.

Fig. 9.1 Transmittance of light through sample and reference cells. The transmittance of the sample vs. the reference cell is then I_S/I_R . I_0 , Intensity of incident light; I_R , intensity of transmitted light through a reagent blank in the reference cell; I_S , intensity of transmitted light for the compound in solution.

Relationship Between Transmittance and Absorbance

When an incident light beam with intensity I_0 passes through a square cell containing a solution of a compound that absorbs light of a specific wavelength, λ (Fig. 9.1), given that the intensity of the transmitted light beam is I_S , the **transmittance** (T) of light is defined as:

$$T = \frac{I_S}{I_0} \quad (9.1)$$

However, some of the incident light may be reflected by the surface of the cell or absorbed by the cell wall or solvent. These factors are eliminated by using a reference cell identical to the sample cell, except that the compound of interest is omitted from the solvent in the reference cell. The transmittance through this reference cell is I_R divided by I_0 ; the transmittance for the compound in solution then is defined

Fig. 9.2 Absorbance and %T relationship.

as I_S divided by I_R . In practice the reference cell is inserted and the instrument adjusted to an arbitrary scale reading of 100 (corresponding to 100% transmittance), after which the percent transmittance reading is made on the sample. The amount of light absorbed (A) as the incident light passes through the sample is equivalent to:

$$A = -\log \left(\frac{I_S}{I_R} \right) = -\log T \quad (9.2)$$

Beer's Law

Beer's law states that the concentration of a substance is directly proportional to the amount of light absorbed:

$$A = abc \quad (9.3)$$

where A = absorbance; a = proportionality constant defined as **absorptivity**; b = light path in centimeters; and c = concentration of the absorbing compound.

Because of the relationship between absorbance and transmittance (Eq. 9.2), concentration is also inversely proportional to the logarithm of the transmitted light (Fig. 9.2). Beer's law forms the basis of quantitative analysis by absorption photometry. **Absorbance (A)** values have no units; hence, the units for a are the reciprocal of those for b and c . When b is 1 cm and c is expressed in moles per liter, the symbol ϵ (epsilon) is substituted for the constant a . The value for ϵ is a constant for a given compound at a given wavelength under prescribed conditions of solvent, temperature, pH, etc., and is called the **molar absorptivity (ϵ)**. The nomenclature of spectrophotometry is summarized in Table 9.3.

Application of Beer's Law

In practice, the direct proportionality between absorbance and concentration must be established experimentally for a given instrument under specified conditions. Frequently, a linear relationship exists up to a certain concentration or absorbance. When this relationship occurs, the solution is said to obey Beer's law up to this point. Within this limitation, a calibration constant (K) may be obtained through measurement of the absorbance of a calibrator of known concentration, and used to calculate the concentration of an unknown solution (c_u) from the measured absorbance (A_u):

$$c_u = A_u \times K \quad (9.4)$$

TABLE 9.3 Spectrophotometry Nomenclature

Name	Symbol	Definition
Absorbance	A	$\log T$ or $\log I_0/I$
Absorptivity	a	A/bc (c in g/L)
Molar absorptivity	ϵ	A/bc (c in mol/L)
Path length	b	Internal cell or sample length, in cm
Transmittance	T	I/I_0^a
Wavelength unit	nm	10^{-9} m
Absorption maximum	$\lambda_{\max}$	Wavelength at which maximum absorption occurs

^a I/I_0 is the ratio of the intensity of transmitted light to incident light.

Certain precautions must be observed with the use of such calibration constants. Under no circumstances should the constant be used when the calibrator or unknown readings exceed the linear portion of the calibration curve (i.e., when the curve no longer obeys Beer's law). At least two or preferably more calibrators should be included in the generation of a calibration curve. A nonlinear calibration curve may be used if a sufficient number of calibrators of varying concentrations are included to cover the entire range encountered for readings on unknowns.

In addition, Beer's law is followed only if the following conditions are met:

- Incident radiation on the substance of interest is monochromatic.
- The solvent absorption is insignificant, compared with the solute absorbance.
- The solute concentration is within given limits.
- An optical interferent is not present.
- A chemical reaction does not occur between the molecule of interest and another solute or solvent molecule.

Measurement Errors

With most photometers, the response of the detector to a signal of transmitted light is such that any uncertainty in %T is constant over the entire %T scale. The uncertainty derives from electrical and mechanical imperfections in the instrument and individual variations in the use of the instrument.

A fixed distance on the linear scale (e.g., 1% T) represents a greater change in absorbance for low values of %T than for high values of %T. For this reason, the absolute concentration error or uncertainty is greater when readings are taken at high absorbance. However, the relative concentration error is greater for readings at both low and high absorbances. The relative error is minimal at an absorbance of 0.434 (36.8% T). Consequently, methods should be designed within an absorbance interval of approximately 0.1 and 0.7 (20% and 80% T).

INSTRUMENTATION

Modern instruments isolate a narrow wavelength range of the spectrum for measurements. Those that use filters for this purpose are referred to as *filter photometers*; those that use prisms

Fig. 9.3 Single-beam spectrophotometer.

Fig. 9.4 Double-beam spectrophotometer.

or gratings are called *spectrophotometers*. Spectrophotometers are classified as single- or double-beam.

The major components of a single-beam spectrophotometer are shown schematically in Fig. 9.3. With such an instrument, a beam of light is passed through a monochromator that isolates the desired region of the spectrum to be used for measurements. Slits are used to isolate a narrow beam of the light and improve its chromatic purity. The light next passes through an absorption cell (cuvet) where a portion of the radiant energy is absorbed, depending on the nature and concentration of the substance in the solution. Any light not absorbed is transmitted to a detector (photo-cell or phototube), which converts light energy to electrical energy that is registered on a meter or recorder or digitally displayed.

In manual operation, an opaque block is substituted for the cuvet, so that no light reaches the photocell, and the meter is adjusted to read 0% T. Next, a cuvet containing a reagent **blank** is inserted, and the meter is adjusted to read 100% T (zero absorbance). The composition of the reagent blank should be identical to that of calibrating or unknown solutions except for the absorbing substance to be measured. Calibrating solutions containing various known concentrations of the substance are inserted, and readings are recorded. Finally, a reading is made of the unknown solution, and its concentration is determined by comparison with readings obtained on the calibrators. With most spectrophotometers, digital hardware and software are integral components that automate blanking and calibrating procedures.

Fig. 9.4 illustrates a typical double-beam instrument that uses a light-beam chopper (a rotating wheel with alternate silvered sections and cutout sections) inserted after the exit slit.

A system of mirrors passes portions of the light reflected off the chopper alternately through the sample and a reference cuvet onto a common detector. The chopped-beam approach, using one detector, compensates for light source variation and for sensitivity changes in the detector.

Components

The basic components of a spectrophotometer include (1) a light source, (2) a means to isolate light of a desired wavelength, (3) fiber optics, (4) cuvetts, (5) a photodetector, (6) a readout device, (7) a computer, and (8) a recorder.

Light Sources

Types of light sources used in spectrophotometers include incandescent lamps, light emitting diodes (LEDs), and lasers.

Incandescent lamps for measuring the visible portion of the spectrum include a tungsten light bulb, a quartz-halogen lamp, hydrogen and deuterium lamps, high-pressure mercury and xenon arc lamps, and zinc hollow cathode lamps.

An LED is a p-n junction diode that emits light when activated. Advantages of this type of light source include a wide range of wavelengths (infrared to UV), low power consumption, and long lifetimes.

A laser (light amplification by stimulated emission of radiation) is a device that may also be used as a light source in spectrophotometers. These devices transform light of various frequencies into an extremely intense, focused, and nearly nondivergent beam of monochromatic light. Through the selection of different materials, different wavelengths of light emitted by the laser are obtained. Examples of laser sources include argon, fluoride, nitrogen, neodymium-YAG (yttrium aluminum garnet), and carbon dioxide lasers.

Spectral Isolation

A system for isolating radiant energy of a desired wavelength and excluding that of other wavelengths is called a *monochromator*. Devices used for spectral isolation include (1) filters, (2) prisms, and (3) diffraction gratings. In addition, combinations of lenses and slits are often inserted before or after the monochromatic device to render light rays parallel, or to isolate narrow portions of the light beam. Variable slits also are used to permit adjustments in total radiant energy reaching the photocell.

Filters. The simplest type of filter is a thin layer of colored glass. Strictly speaking, a glass filter is not a true monochromator because it transmits light over a relatively wide range of wavelengths. The spectral purity of a filter or other monochromator is usually described in terms of its **spectral bandwidth**. This is defined as the width, in nanometers, of the spectral transmittance curve at one-half the peak transmittance. Commonly used glass filters have spectral bandwidths of approximately 50 nm and are referred to as wide **bandpass** filters.

Other glass filters include narrow bandpass and sharp-cut-off types. Operationally, a cutoff filter typically shows a sharp rise in transmittance over a narrow portion of the spectrum and is used to eliminate light below or above a given wavelength. Narrow bandpass filters are constructed by combining two or more sharp-cut-off filters or regular filters.

Interference filters are also used as monochromators. These filters have narrow spectral bandwidths, usually from 5 to 15 nm. Because they also transmit harmonics, or multiples, of the desired wavelength, accessory glass filters are required to eliminate these undesired wavelengths. Thus an interference filter designed for 620 nm will also transmit some radiation at 310 and 1240 nm unless accessory cutoff filters are provided to absorb this undesired stray light.

Prisms and gratings. Prisms and diffraction gratings are also widely used as monochromators. A prism separates white light into a continuous spectrum by refraction with shorter wavelengths bent, or refracted, to a greater extent than longer wavelengths as they pass through the prism. A diffraction grating is prepared by depositing a thin layer of aluminum-copper alloy on the surface of a flat glass plate; then, many small parallel grooves are made in the metal coating. Diffraction gratings are extremely accurate, have low light scatter, and are widely used in the spectrophotometers used in analytical instruments. For example, most UV-visible spectrophotometers and virtually all IR spectrophotometers use reflective gratings. In addition, high performance liquid chromatography (HPLC) detectors frequently use a concave holographic reflective grating in their optical system.

Each groove of the grating, when illuminated, gives rise to a tiny spectrum. Wave fronts are formed that reinforce those wavelengths in phase and cancel those not in phase. The net result is a uniform linear spectrum. Some instruments contain diffraction gratings that produce spectral bandwidths of 20 nm or more; higher-priced instruments may have a resolution of 0.5 nm or less.

A grating may also be ruled at a specified angle, so that a maximum fraction of the radiant energy is directed into wavelengths diffracted at a selected angle. This type of grating is said to have been given a *blaze* at a particular angle or to have been blazed at a certain wavelength (e.g., 250 nm).

Selection of a wavelength isolation device. The type of monochromator chosen depends on the analytical purpose for which it is to be used. For example, narrow spectral bandwidths are required in spectrophotometers for resolving and identifying sharp absorption peaks that are closely adjacent. Lack of agreement with Beer's law will occur when a part of the spectral energy transmitted by the monochromator is not absorbed by the substance being measured. This is more commonly observed with wide bandpass instruments. In practice, an increase in absorbance and improved linearity with concentration are usually observed with instruments that operate at narrower bandwidths of light. This is especially true for substances that exhibit a sharp peak of absorption. The natural bandwidth of an absorbing substance is defined as "the bandwidth of the spectral absorbance curve at a point equal to one-half of the maximum absorbance." As a general rule, for peak absorbance readings to be within 99.5% of true values, the spectral bandwidth should not exceed 10% of the natural bandwidth. For example, many chemistry procedures used in the clinical laboratory produce an absorbing species for which the natural bandwidth ranges from 40 to greater than 200 nm. The natural bandwidth of NADH is 58 nm ($\lambda_{\text{max}} = 339 \text{ nm}$). Therefore, for accurate measurements of this compound, an instrument should be used that has a spectral bandwidth of 6 nm or less.

In practice, the wavelength selected is usually at the peak of maximum absorbance to achieve maximum sensitivity; however, it may be desirable to choose another wavelength to minimize interfering substances. For example, turbidity readings on a spectrophotometer are greater in the blue region than in the red region of the spectrum, but the latter region is chosen for turbidity measurements to avoid absorption of light by bilirubin (460 nm) or hemoglobin (417 and 575 nm). In addition, measurements should not be taken on the steep slope of an absorption curve because a slight error in wavelength adjustment will introduce a significant error in absorbance readings.

Fiber Optics

In the single- and double-beam spectrophotometers shown diagrammatically in Figs. 9.3 and 9.4, the positioning of the individual components dictates the path that the light beam must follow as it travels from the source to the detector. This approach places certain restrictions on the (1) design, (2) size, and (3) cost of such instruments. To overcome these restrictions, fiber optics are now integrated into the optical design of spectrophotometers. Fiber optics, also known as *light pipes*, are bundles of thin, transparent fibers of glass, quartz, or plastic that are enclosed in material of a lower index of refraction and that transmit light throughout their lengths by internal reflections. The use of fiber optics in spectrophotometers offers the advantage of better directional control of the beam

of light within the geometrical confines of an instrument. This allows for the design and manufacture of miniature and inexpensive optical subsystems for use in automated instruments. For example, a single light source is multiplexed with multiple detectors by fiber optics for optimal positioning of the source and detectors in an automated system. Disadvantages of fiber optics include (1) greater amounts of stray light; (2) refractive index changes in the glass, quartz, or plastic rods; and (3) loss of transmitted energy after continued use in the UV region of the spectrum. This loss of energy is known as *solarization* and results in a decrease in the optical performance of an instrument.

Cuvets

A cuvet (or cuvette) is a small vessel used to hold a liquid sample to be analyzed in the light path of a spectrometer. Cuvets may be (1) round, (2) square, or (3) rectangular and are constructed from (1) glass, (2) silica (quartz), or (3) plastic. Square or rectangular cuvettes have plane-parallel optical surfaces and a constant light path. Most have a 1.0 cm light path, held to close tolerances. Ordinary borosilicate glass cuvettes are suitable for measurements in the visible portion of the spectrum. However, for readings below 340 nm quartz cells are usually required. Some plastic cells have good clarity in both visible and UV ranges but often present problems related to (1) tolerance, (2) cleaning, (3) etching by solvents, and (4) temperature deformation. Many plastic cuvettes are designed for disposable, single-use applications.

Photodetectors

Photodetectors are devices that convert light into an electrical signal that is proportional to the number of photons striking its photosensitive surface. The photomultiplier tube (PMT) is a photodetector that is commonly used to measure light intensity in UV and visible regions of the spectrum. PMTs (1) have extremely rapid response times, (2) are very sensitive, and (3) are slow to fatigue.

Photodiodes also are used as photodetectors. They are solid-state devices that are fabricated from photosensitive semiconductor materials, such as (1) silicon, (2) gallium arsenide, (3) indium antimonide, (4) indium arsenide, (5) lead selenide, and (6) lead sulfide. These materials absorb light over a characteristic wavelength range (e.g., 250 to 1100 nm for silicon). Their development and use as detectors in spectrophotometers have resulted in instruments capable of measuring light at a multitude of wavelengths. When a photodetector consists of multiple diodes in an array, each of which responds to a specific wavelength, it is known as a *photodiode array*. For example, photodiode arrays have been designed to have a 2 nm resolution per diode from 200 to 340 nm, and a 1 nm resolution per diode from 340 to 800 nm.

Readout Devices

Electrical energy from a detector is displayed on a digital readout device (e.g., a bank of light-emitting diodes) that provides a visual numerical display of absorbance or converted values of concentrations.

Digital Hardware and Software Computers

Various types of digital hardware, with resident software and processors, are incorporated and integrated into both photometers and spectrophotometers. For example, with a resident computer and software (1) output from a calibrator is digitally stored, (2) digital signals from a blank is subtracted from the calibrator and the unknown, and (3) the concentration of unknown is automatically calculated. Data from multiple calibrators often are used to (1) store a complete calibration curve, (2) display or print out the curve for visible inspection, and (3) calculate the results of unknowns based on the curve or some mathematical transformation of the data. Computers and their resident software also are used to convert kinetic data into concentration or enzyme activity.

Recorders

Historically, spectrophotometers were equipped with recorders in addition to or instead of a digital display. These were synchronized to provide line traces of transmittance or absorbance as a function of time or wavelength. When a continuous tracing of absorbance versus wavelength is recorded, the resultant figure is called an *absorption spectrum*. If a substance absorbs light, distinct peaks of absorbance will be observed. Measuring the absorption spectra of an unknown sample and comparing them with spectra from known compounds is very useful for qualitative purposes.

Performance Parameters

In most spectrophotometric analytical procedures, the absorbance of an unknown sample is compared directly with that of a calibrator or a series of calibrators. Under these circumstances, (1) minor errors in wavelength calibration, (2) variations in spectral bandwidths, and (3) the presence of stray light are compensated for and do not usually contribute to serious errors. The use of a series of calibrators covering a wide range of concentrations also provides a measure of linearity and validation of agreement with Beer's law for a given procedure and instrument. However, when calculations are based on published or previously determined values for molar absorptivities or absorption coefficients, the spectrophotometer must be checked more rigorously.

The National Institute of Standards and Technology (NIST) provides several standard reference materials (SRMs) for spectrophotometry that are useful in the calibration or verification of the performance of photometers or spectrophotometers (e.g., SRM 930e is used for the verification and calibration of the transmittance and absorbance scales of visible absorption spectrometers) (<http://www.nist.gov/srm>). The Institute for Reference Materials and Measurements (IRMM), a metrology institute that belongs to the European Commission, also provides reference materials for verification of the performance of photometers or spectrophotometers (<https://ec.europa.eu/jrc/en/news/welcome-irmm-reference-materials-catalogue-9438>).

Fig. 9.5 Atomic absorption spectrophotometer.

REFLECTANCE PHOTOMETRY

In **reflectance photometry**, diffused light illuminates a reaction mixture in a carrier, and the reflected light is measured. Alternatively, the carrier is illuminated and the reaction mixture generates a diffuse reflected light, which is measured. The intensity of the reflected light from the reagent carrier is compared with the intensity of light reflected from a reference surface. Because the intensity of reflected light is nonlinear in relation to the concentration of the analyte, transformations are commonly used to convert the data into a linear format. The electro-optical components used in reflectance photometry are essentially the same as those required for absorbance photometry. Reflectance photometry is used as the measurement method with dry-film chemistry systems.

ATOMIC ABSORPTION SPECTROPHOTOMETRY

Atomic absorption (AA) spectrophotometry is used in clinical laboratories to measure elements such as aluminum, calcium, copper, lead, lithium, magnesium, zinc, and other metals. A method for metal analysis that has begun to replace AA is ICP-MS (inductively coupled plasma mass spectrometry). Atomic absorption retains advantages over ICP-MS in terms of overall cost and ease of use. However, a single ICP-MS instrument has greater flexibility in measuring multiple metals simultaneously and with greater sensitivity (see Chapter 13).

Basic Concepts

AA is an optical technique in which an ion in the sample is converted to a ground state atom of that element by a flame or graphite furnace, and introduced into the light path of a spectrophotometer. The ground state atom is capable of absorbing radiation at a very narrow bandwidth corresponding to its own line spectrum. A hollow-cathode lamp with the cathode made of the material to be analyzed is used to produce a wavelength of light specific for the material. Thus, if the cathode was made of calcium, light at predominantly 423 nm would be emitted by the lamp. When the light from the hollow-cathode lamp enters the flame, some of it is absorbed by the ground-state atoms in the flame, resulting in a net decrease in the intensity of the beam from the lamp. This process is referred to as *atomic absorption*. Owing to the unique specificity of the wavelength from the hollow-cathode lamp, these methods are highly specific for the element being measured.

Instrumentation

The components of an AA spectrophotometer are shown in Fig. 9.5. A hollow-cathode lamp serves as the light source for an AA spectrophotometer. Such lamps are made of the metal of the substance to be analyzed; this is different for each metal analysis. When an alloy is used to make the cathode, the result is a multielement lamp.

With flameless AA techniques (carbon rod or “graphite furnace”), the sample is placed in a depression on a carbon rod in an enclosed chamber. Strips of tantalum or platinum metal are used as sample cups. In successive steps, the temperature of the rod is raised to dry, char, and finally atomize the sample in the chamber. The atomized element then absorbs energy from the corresponding hollow-cathode lamp. This approach is very sensitive and permits determination of trace metals in small samples of blood or tissue. However, background absorbance by molecules and particulate matter from the sample may limit the sensitivity of the method.

With flameless AA, background absorption can be corrected by placing the analyte in a strong magnetic field. The intense magnetic field splits the degenerate (i.e., of equal energy) atomic energy levels into two components that are polarized parallel and perpendicular to the magnetic field, respectively. The parallel component is at the resonance line of the source, whereas the two perpendicular components are shifted to different wavelengths. The two components interact differently with polarized light. A polarizer is placed between the source and the atomizer, and two absorption measurements are taken at different polarizer settings. One measures both analyte and background absorptions (A_t), the other only background absorption (A_{bc}). The difference between the two absorption readings is the corrected absorbance.

The major advantage of magnetic correction is that the same light source at the same wavelength is used to measure total and background absorption. Implementation is complex and expensive, and the strength of the magnetic field needs to be optimized for every element, but the method gives more accurate results at higher background levels than are associated with other correction techniques.

Limitations of Atomic Absorption Spectrophotometry

Spectral and nonspectral interferences are limitations of AA spectroscopy.

Spectral Interferences

Spectral interferences include (1) absorption by other closely absorbing atomic species, (2) absorption by molecular species, (3) scattering by nonvolatile salt particles or oxides, and

(4) background emission (which is corrected for by electronic filtering). Absorption by other atomic species usually is not a problem because of the extremely narrow bandwidth (0.01 nm) of the light generated by a hollow cathode lamp that is used in AA instruments. Absorption and scattering by molecular species are particularly problematic at lower atomizing temperatures.

Nonspectral Interferences

Nonspectral interferences may be nonspecific or specific. Nonspecific interferences affect nebulization by altering the (1) viscosity, (2) surface tension, or (3) density of the analyte solution, and consequently the sample flow rate. Specific interferences (chemical interferences) are analyte dependent. *Solute volatilization interference* refers to the situation in which the contaminant forms nonvolatile species with the analyte. An example is seen in phosphate interference in the determination of calcium that is caused by the formation of calcium-phosphate complexes. The phosphate interference is eliminated by adding a cation, usually lanthanum or strontium that competes with calcium for the phosphate. Enhancement effects are also observed, in which the addition of contaminants increases the volatilization efficiency. Such is the case with aluminum, which normally forms nonvolatile oxides, but in the presence of hydrofluoric acid forms more volatile aluminum fluoride. Dissociation interferences affect the degree of dissociation of the analyte. Analytes that form oxides or hydroxides are especially susceptible to dissociation interferences. Ionization interference occurs when the presence of an easily ionized element, such as K, affects the degree of ionization of the analyte, which leads to changes in the analyte signal. In cases of excitation interference, the analyte atoms are excited in the atomizer, with subsequent emission at the absorption wavelength. This type of interference is more pronounced at higher temperatures.

FLUOROMETRY

Fluorescence occurs when a molecule absorbs light at one wavelength and reemits light at a longer wavelength. An atom or molecule that fluoresces is termed a *fluorophore*. **Fluorometry** is defined as the measurement of emitted fluorescence light. Fluorometric analysis is a very sensitive and widely used method of quantitative analysis in the chemical and biological sciences.

Basic Concepts

The relationship between (1) absorption, (2) fluorescence, and (3) phosphorescence is shown in Fig. 9.6. As indicated, each molecule contains a series of closely spaced energy levels. Absorption of a quantum of light energy by a molecule causes the transition of an electron from the singlet ground state to one of a number of possible vibrational levels of its first excited singlet state. The actual number of molecules in the excited state under typical reaction conditions and excited with a typical 150-W light source is very small and is estimated to be about 10^{-13} mole per mole of fluorophore.

Fig. 9.6 Luminescence energy-level diagram of typical organic molecule. A, Absorption process; F, fluorescence process from the first excited singlet state; P, phosphorescence process from the first excited triplet state; Q, quenching of the excited singlet or triplet state; RC, radiation-less crossover from the first excited singlet state to the first excited triplet state; RVD, radiation-less vibrational deactivation; S_0 , ground level singlet state; S_1 , first excited singlet state; T_1 is the first excited triplet state.

Once the molecule is in an excited state, it returns to its original energy state by different mechanisms. These include (1) radiation-less vibrational equilibration, (2) the fluorescence process, (3) quenching of the excited singlet state, (4) radiation-less crossover to a triplet state, (5) quenching of the first triplet state, and (6) the phosphorescence process.

As shown in Fig. 9.6, vibrational equilibration before fluorescence results in some loss of excitation energy. The emitted fluorescence light is therefore of less energy and has a longer wavelength than the excitation light. The difference between the maximum wavelength of the excitation light and the maximum wavelength of the emitted fluorescence light is a constant for a given molecule, referred to as the *Stokes shift*. This constant is a measure of energy lost during the lifetime of the excited state (radiation-less vibrational deactivation) before returning to the ground singlet level (fluorescence emission).

Time Relationships of Fluorescence Emission

The time required for a molecule to absorb radiant energy and to be promoted to an excited state is approximately 10^{-15} s. The length of time needed for vibrational equilibration to occur to the lowest excited state is of the order of 10^{-14} to 10^{-12} s. The length of time required for fluorescence emission to occur is of the order of 10^{-8} to 10^{-7} s. Relatively speaking, there is a considerable time delay between (1) absorption of light energy, (2) return to the lowest excited state, and (3) emission of fluorescence light. This time relationship is shown in Fig. 9.7. Phase I represents the time period between the absorbance of light energy and the radiation-less loss of energy during vibrational rearrangement to the lowest excited energy state. This time period is represented by the up and down arrows in the diagram. Phase II shows the emission and decay of a short-lived (b) and a longer-lived (a) fluorophore. If the fluorescence emission is measured over time following a pulse of light from an excitation source, such as a xenon lamp or laser, the intensity of the emitted

Fig. 9.7 Fluorescence decay process. *a*, Long fluorescence decay time; *b*, short fluorescence decay time; *E*, absorption of energy; *I*, vibrational deactivation time phase; *II*, fluorescence emission time phase.

light decays as a first-order process similar to radioactive decay. The time required for the emitted light to reach $1/e$ of its initial intensity, where e is the Naperian base 2.718, is the average lifetime of the excited state of the molecule, or the fluorescence decay time.

The time delay between absorption of energy and fluorescence is used in a fluorescence instrument called a *time-resolved fluorometer*. Advantages of a time-resolved fluorometer include the elimination of background light scattering and background from short-lived fluorescence. This results in a dramatic increase in the signal-to-noise ratio and detection sensitivity.

Depending on how the fluorescence emission response is measured, time-resolved fluorometry is categorized as pulse or phase fluorometry. In pulse fluorometry, the sample is illuminated with an intense brief pulse of light, and the intensity of the resulting fluorescence emission is measured as a function of time with a fast detector system. In phase fluorometry, a continuous-wave laser illuminates the sample, and the fluorescence emission response is monitored for impulse and frequency response.

Relationship of Concentration and Fluorescence Intensity

The relationship of concentration to the intensity of fluorescence emission is derived from Beer's law and is expressed as:

$$F = \Phi I_0 \epsilon b c \quad (9.5)$$

where F = relative intensity; Φ = fluorescence efficiency (i.e., the ratio between quanta of light emitted and quanta of light absorbed); I_0 = initial excitation intensity; ϵ = molar absorptivity; b = volume element defined by geometry of the excitation and emission slits; and c = the concentration in mol/L.

Eq. 9.5 indicates that fluorescence intensity is directly proportionate to the concentration of the fluorophore and the intensity of the excitation. This relationship holds only for dilute solutions in which absorbance is less than 2% of the exciting radiation. Above 2%, the fluorescence intensity becomes nonlinear. This phenomenon is called the *inner filter*

effect, and it is discussed in greater detail in a later section. Other factors influencing the measurement of fluorescence intensity are the sensitivity of the detector and the degree of background light scatter seen by the detector.

Fluorescence intensity measurements are more sensitive than absorbance measurements. The magnitude of absorbance of a chromophore in solution is determined by its concentration and the path length of the cuvet. The magnitude of the fluorescence intensity of a fluorophore is determined by (1) its concentration, (2) the path length, and (3) the intensity of the light source. Comparatively, fluorescence measurements are 100 to 1000 times more sensitive than absorbance measurements. This is due to the use of (1) more intense light sources, (2) digital signal filtering techniques, and (3) sensitive emission photometers.

Frequently, fluorescence measurements are expressed in relative intensity units. The word *relative* is used because the intensity measured is not an absolute quantity. It is a small part of the total fluorescence emission, and its magnitude is defined by (1) instrument slit width, (2) detector sensitivity, (3) monochromator efficiency, and (4) excitation intensity. Because these are instrument-related variables, establishing an absolute intensity unit for a given concentration of a fluorophore that is valid from instrument to instrument is difficult, if not impossible.

Fluorescence Polarization

Light is composed of electrical and magnetic waves at right angles to each other. Light waves produced by standard excitation sources have their electrical vectors oriented randomly. Light waves passed through certain crystalline materials (polarizers) have their electrical vectors oriented in a single plane and are said to be plane-polarized. Fluorophores absorb light most efficiently in the plane of their electronic energy levels. If their rotational relaxation (Brownian movement) is slower than their fluorescence decay time—as is the case for large fluorescent-labeled molecules—the emitted fluorescence light will remain polarized. Because small molecules have rotational relaxation times that are much shorter than their fluorescence decay time, their emitted fluorescence light is depolarized. However, if the small fluorescent molecule is attached to a macromolecule, or if it is placed in a viscous solution, the small molecule will emit polarized light. Fluorescence polarization (P) is defined by the following equation:

$$P = \frac{I_v - I_h}{I_v + I_h} \quad (9.6)$$

where I_v = intensity of emitted fluorescence light in the vertical plane; and I_h = intensity of emitted fluorescence light in the horizontal plane.

As indicated, P is the difference between the two observed intensities divided by their sum. Fluorescence polarization is measured by placing a mechanically or electrically driven polarizer between the sample cuvet and the detector. In the normal instrumentation mode, the sample is excited with polarized light to obtain maximum sensitivity. The polarization analyzer is positioned to measure the intensity of emitted

fluorescence light in the vertical plane (I_v), and then the polarization analyzer is rotated 90 degrees to measure emitted fluorescence light intensity in the horizontal plane (I_h). P is then calculated manually or automatically by using Eq. 9.6.

Fluorescence polarization is used to quantify analytes by using the change in fluorescence depolarization following immunologic reactions (see Chapter 15). Quantification is accomplished by adding a known quantity of fluorescent-labeled analyte molecules to a reaction solution containing an antibody specific to the analyte. The labeled analyte binds to the antibody, and the slowed rotation and longer relaxation time results in an increased degree of fluorescence polarization. The addition of a nonlabeled analyte, such as an unknown quantity of a therapeutic drug in a serum specimen, will result in competition for binding to the antibody with the fluorescent-labeled analyte. This change in binding of the fluorophore-labeled analyte causes a change in fluorescence polarization that is inversely proportional to the amount of analyte contained in a given sample. Because the change in fluorescence polarization is a direct response to the reaction mixture, the bound fluorophore need not be separated from free fluorophore. Thus fluorescence polarization is applicable to homogeneous assays of low-molecular-weight analytes, such as therapeutic drugs.

Instrumentation

Fluorometers and spectrofluorometers are used to measure fluorescence. Operationally, a fluorometer uses interference filters or glass filters to produce monochromatic light for sample excitation and for isolation of fluorescence emission, whereas a spectrofluorometer uses a grating or prism monochromator.

Components

Basic components of fluorometers and spectrofluorometers include (1) an excitation source, (2) an excitation monochromator, (3) a cuvet, (4) an emission monochromator, and (5) a detector. In Fig. 9.8, these components are shown as they would be configured in a 90-degree optical system.

With fluorometers and spectrofluorometers, the placement of the cuvet and the excitation beam relative to the photodetector is critical in establishing the optical geometry for fluorescence measurements. As fluorescence light is emitted in all directions from a molecule, several excitation/emission geometries are used to measure fluorescence (Fig. 9.9). Most commercial spectrofluorometers and fluorometers use the right angle detector approach because it minimizes the background signal that limits analytical detection. The end-on approach allows the adaptation of a fluorescence detector to existing 180 degrees absorption instruments. Its limit of detection is restricted by (1) the quality of the excitation and/or emission interference filter pair, (2) the excitation and/or emission spectral band overlap, and (3) the inner filter effect (which is discussed later). The front surface approach provides the greatest linearity over a broad range of concentration because it minimizes the inner filter effect. The front surface approach has a comparable limit of detection to right

Fig. 9.8 Block diagram of a typical spectrofluorometer. A_1 and A_2 , Excitation signal and emission signal amplifiers, respectively; C , sample cell; D_1 and D_2 , detectors (D_1 monitors the variation in excitation intensity and D_2 measures fluorescence emission intensity); M_1 , excitation monochromator; M_2 , emission monochromator; PS , power supply; XS , xenon source.

angle detectors but is more susceptible to background light scatter. Front surface fluorometry has been widely applied to heterogeneous solid phase fluorescence immunoassay systems.

To accommodate these different geometries, the sample cell is oriented at different angles in relation to the excitation source and the detector. Major concerns related to the geometry of the sample cell are (1) light scattering, (2) the inner filter effect, and (3) the sample volume element seen by the detector. Fig. 9.10 shows the sample cell and slit arrangement for a conventional fluorescence spectrophotometer with excitation and emission slits oriented at a right angle. $Slit_1$ and $Slit_2$ designate the excitation and emission slits, respectively. The position of the emission slit and the width of the slit are important. If the emission slit is located near the front edge of the sample cell, as shown in Fig. 9.10B, the inner filter effect is minimized. If the emission slit width is increased, the detector will be more sensitive, but specificity may decrease.

Performance Verification

As with spectrophotometers, NIST provides a number of SRMs for use in calibration or verification of the performance of fluorometers or fluorospectrophotometers. These include SRM 936a (quinine sulfate dihydrate) for calibration and SRM 1932 (fluorescein) for establishing a reference scale for fluorescence measurements (see <http://www.nist.gov/srm>).

Types of Fluorometers and Spectrofluorometers

Fluorometers and fluorescence spectrophotometers are available that offer a variety of features. These features include (1) ratio referencing, (2) computer-controlled excitation and emission monochromators, (3) pulsed xenon light sources, (4) photon counting, (5) a rhodamine cell for corrected spectra, (6) polarizers, (7) flow cells, (8) front surface viewing adapters, (9) multiple cell holders, and (10) computer-based data reduction systems.

In addition to the basic spectrofluorometer discussed earlier (see Fig. 9.8), other types of fluorometric instruments include (1) a ratio-referencing spectrofluorometer, (2) a time-resolved fluorometer, (3) a flow cytometer, and (4) a hematofluorometer.

Ratio-referencing spectrofluorometer. A typical ratio-referencing spectrofluorometer is illustrated in Fig. 9.11. Basically, this is a simple right-angle instrument that uses two monochromators (*M1* and *M2*), two PMT detectors (*D1* and *D2*, the reference and sample PMTs), and a xenon lamp source. The light from the exciter monochromator (*M1*) is split, and a small portion (10%) is directed to the reference PMT (*D1*) for ratio-referencing purposes. The remaining excitation light is focused into the sample cuvet (*C*). Emission

Fig. 9.10 Two right-angle fluorescence sample cuvet positions. (A) The standard 90 degrees configuration. (B) The offset positioning of the cuvet to minimize the inner filter effect. *D*, Detector; *EmM*, emission monochromator; *ExM*, excitation monochromator; I_0 , initial excitation energy; I_f , fluorescence intensity; *S*, source.

optics are positioned at a right angle to the excitation optics. An emission monochromator (*M2*) is used to select or scan the desired portion of the emission spectra, which is directed to the sample PMT (*D2*) for measurement of emission intensity. The output signals from the reference and from the sample PMTs are amplified (*A1* and *A2*), and a ratio of the sample to the reference signal is provided by a digital display or a chart recorder. The operational mode of a ratio fluorometer is similar to that of a spectrofluorometer; however, only discrete excitation and emission wavelengths are available, and the use of this type of instrument is precluded from scanning fluorophores to obtain emission and excitation spectra. The ratio filter fluorometer is most useful for obtaining concentration measurements at defined excitation and emission wavelengths.

The ratio-referencing spectrofluorometer is operated at fixed excitation and emission wavelength settings for

Fig. 9.11 Diagram of a typical ratio-referencing spectrofluorometer.

concentration measurements, or it is used to measure the excitation or emission spectrum of a given compound. Measurement of the concentration of unknowns is accomplished in a similar manner as with a single-beam fluorometer. A blank solution and a calibrating solution are first measured, and then the unknown samples are measured. The ratio-referencing spectrofluorometer in Fig. 9.11 provides two advantages over single-beam spectrofluorometers. First, it eliminates short- and long-term xenon lamp energy fluctuations (i.e., arc flicker and lamp decay), thus minimizing the need for frequent calibration of the instrument during analysis. Second, it provides excitation spectra, which are corrected for wavelength-dependent energy fluctuations.

Time-resolved fluorometers. A time-resolved fluorometer is similar to the ratio-referencing fluorometer, with the exception that the light source is pulsed and the detector monitors, in a fast photon-counting mode, the exponential decay of the fluorescence signal after excitation. Time-resolved fluorometry requires the use of long-lived fluorophores, such as the lanthanide (rare earth) metal ions europium (Eu^{3+}) and samarium (Sm^{3+}). Whereas most fluorescence compounds have decay times of 5 to 100 ns, europium chelates decay in 0.6 to 100 s. Thus time-resolved fluorescence assays take advantage of the difference in the lifetimes of fluorophore and background fluorescence by measuring the decaying fluorescence signal. This eliminates background interferences and at the same time averages the signal to improve the precision of measurement. Detection limits of approximately 10^{-13} mol/L have been achieved with time-resolved fluorometry, for an improvement of about four orders of magnitude

compared with conventional fluorometric measurements. For example, Eu^{3+} -labeled nanoparticles in combination with time-resolved fluorometry have been used to develop a highly sensitive immunoassay for free and a total prostate-specific antigen with a functional sensitivity of 0.5 ng/L.

Flow cytometry. Cytometry refers to the measurement of physical and/or chemical characteristics of cells or particles. Flow cytometry is a process in which such measurements are made while cells or particles pass, preferably in single file, through the measuring apparatus in a fluid stream. Flow sorting extends flow cytometry by using electrical or mechanical means to divert and collect cells with one or more measured characteristics falling within a range of values set by the user.

Operationally, flow cytometry combines laser-induced fluorometry and particle light-scattering analysis that allow different populations of (1) molecules, (2) cells, or (3) particles to be differentiated by size and shape using low-light and right-angle light scattering. The use of a laser is ideally suited for low-angle light scattering. These cells, molecules, or particles are labeled with different specific fluorescent labels, such as (1) β -phycoerythrin, (2) fluorescein isothiocyanate, (3) rhodamine-6G, and (4) dye-labeled antibodies. As the particles flow through the flow cell, simultaneous fluorescence and light-scattering measurements are automatically performed by the flow cytometer. Most flow cytometers incorporate two or more fluorescence emission detection systems so that multiple fluorescent labels are able to be used. In this manner, molecules, cells, and particles are classified by (1) size, (2) shape, and (3) type according to their light-scattering and fluorescent properties. A schematic diagram of a flow cytometer is shown in Fig. 9.12.

Fig. 9.12 Schematic diagram of a flow cytometer. PMT, Photomultiplier tube.

Flow cytometers are able to measure multiple parameters, including (1) cell size (forward scatter), (2) granularity (90-degree scatter), (3) DNA and RNA content, (4) DNA (AT)/(GC) nucleotide ratios, (5) chromatin structure, (6) antigens, (7) total protein content, (8) cell receptors, (9) membrane potential, and (10) calcium ion concentration as a function of pH. In particle-based flow cytometry, a flow cytometer is combined with microspheres that are used as the solid support for conventional immunoassay, affinity assay, or DNA hybridization assays. The microspheres contain different proportions of two fluorescent dyes to generate 100 or more different signatures. Each of these signatures can be assigned to a specific analyte to multiplex many analytes in the same sample. The resulting system is very flexible for small volume assays that simultaneously assess a wide variety of analytes in the same sample.

Hematofluorometer. The *hematofluorometer* is a single-channel front surface photofluorometer dedicated to the analysis of zinc protoporphyrin in whole blood (see Chapter 29). A typical hematofluorometer uses a quartz-tungsten lamp, a narrow bandpass excitation filter (420 nm), front surface optics, a narrow bandpass emission filter (594 nm), and a PMT. A drop of whole blood is placed on a small rectangular glass slide that serves as a cuvet.

Limitations of Fluorescence Measurements

Factors that influence fluorescence measurements include (1) concentration effects (e.g., inner filter effect, concentration quenching), (2) background effects (due to Rayleigh and Raman scattering), (3) solvent effects (e.g., interfering non-specific fluorescence, quenching from the solvent), (4) sample effects (e.g., light scattering, interfering fluorescence, sample adsorption), (5) temperature effects, and (6) photodecomposition (bleaching) of the sample.

Inner Filter Effect

The linear relationship between concentration and fluorescence emission (Eq. 9.5) is valid when solutions absorb less than 2% of the exciting light. As the absorbance of the solution increases above this amount, the relationship becomes nonlinear—a phenomenon known as the *inner filter effect*. It is caused by loss of excitation intensity across the cuvet path length as excitation light is absorbed by the fluorophore. Thus, as the fluorophore becomes more concentrated, absorbance of excitation intensity increases, and loss of excitation light as it travels through the cuvet increases. This effect is most often encountered with a right-angle fluorescence instrument, in which the emission slits are set to monitor the center of the sample cell, where absorbance of excitation light is greater than at the front surface of the cuvet. Therefore it is less problematic if a front surface fluorescence instrument is used. However, most fluorescence measurements are made on very dilute solutions, and the inner filter effect therefore is not a problem.

Concentration Quenching

Another related phenomenon that results in a lower quantum yield than expected is called *concentration quenching*. This occurs when a macromolecule, such as an antibody, is heavily labeled with a fluorophore, such as fluorescein isothiocyanate. When this compound is excited, the fluorescence labels are in such close proximity that a radiation-less energy transfer occurs. Thus the resulting fluorescence is much lower than expected for the concentration of the label. This is a common problem in flow cytometry and in laser-induced fluorescence when attempts are made to enhance detection sensitivity by increasing the density of the fluorescing label.

Light Scattering

Light scattering—Rayleigh and Raman—limits the use of fluorescence measurements. Rayleigh scattering occurs with no change in wavelength. For fluorophores with small Stokes shifts, the excitation and emission spectra overlap and are particularly susceptible to loss of detection caused by background light scatter. Rayleigh scatter is controlled by the use of well-defined emission and excitation interference filters or by appropriate monochromator settings and the use of polarizers.

Raman scattering occurs with the lengthening of the wavelength. This type of light scattering is independent of excitation wavelength and is a property of the solvent. Because Raman light scattering appears at longer wavelengths than the exciting radiation, it is a difficult interference to eliminate when working at very low fluorophore concentrations.

Cuvet Material and Solvent Effects

Certain quartz glass and plastic materials that contain UV absorbers will fluoresce. Some solvents, such as ethanol, are also known to cause appreciable fluorescence. It is therefore important when developing a fluorescence assay to assess the background fluorescence of all components of the reaction mixture.

Sample Matrix Effects

A serum or urine sample contains many compounds that fluoresce. Thus the sample matrix is a potential source of unwanted background fluorescence and must be examined when new methods are developed. The most serious contributors to unwanted fluorescence are proteins and bilirubin. However, because protein excitation maxima are in the spectral region of 260 to 290 nm, their contribution to overall background fluorescence is minor when excitation occurs above 300 nm.

Light scattering of proteins and other macromolecules in the sample matrix has been known to cause unwanted background fluorescence. Lipemic samples, for example, are noted for their intense light scattering, and the relative contribution of lipids to the background signal of a fluorescence measurement should be investigated when a new method is developed.

In addition to background interferences, dilute solutions of some fluorophores in the concentration range of 10^{-9} mol/L and below will absorb to the walls of glass cuvetts and other reaction vessels. Also, dilute solutions of fluorophores, when excited over long periods, are susceptible to photodecomposition by intense excitation light. Operationally, these problems are prevented by (1) selecting proper reaction vessels, (2) adding wetting agents, and (3) minimizing the length of time a sample is exposed to the excitation light.

Temperature Effects

The fluorescence quantum efficiency of many compounds is sensitive to temperature fluctuations. Therefore the temperature of the reaction must be tightly controlled. In general, fluorescence intensity decreases with increasing temperature by approximately 1% to 5% per degree Celsius. Increased

temperatures result in more frequent molecular collisions and quenching. Collisional quenching can be decreased by lowering the temperature or by increasing the viscosity.

Photodecomposition

In conventional fluorometry, excitation of weakly fluorescing or dilute solutions with intense light sources will cause photochemical decomposition of the analyte (photobleaching).

The following steps help to minimize photodecomposition effects:

1. Always use the longest feasible wavelength for excitation that does not introduce light-scattering effects.
2. Decrease the duration of excitation of the sample.
3. Protect unstable solutions from ambient light by storing them in dark bottles.
4. Remove dissolved oxygen from the solution.

Highly intense laser light sources are useful for applications that require higher sensitivity to measure low analyte concentrations (e.g., flow cytometry, fluorescence microscopy). Laser light sources can have energy outputs of 5 to 10 mW, which enable high sensitivity detection; however, these intense light sources rapidly photodecompose some fluorescent analytes. This photodecomposition introduces nonlinear response curves and loss of most of the sample fluorescence. Thus, the optimization of laser intensity balances higher sensitivity with increased photodecomposition.

LUMINOMETRY

Chemiluminescence and **electrochemiluminescence** are types of luminescence in which the excitation event is caused by a chemical, biochemical, or electrochemical reaction, and not by photo illumination. Instruments for measuring this type of light emission are known generically as luminometers.

Basic Concepts

The physical event of light emission in chemiluminescence and electrochemiluminescence is similar to fluorescence in that it occurs from an excited singlet state, and the light is emitted when the electron returns to the ground state.

Chemiluminescence

Chemiluminescence is the emission of light when a molecule returns from an excited or higher energy level to a lower energy level. The excitation event is caused by a chemical reaction with compounds such as luminol and acridinium esters. Light is emitted from the excited product formed in the oxidation reaction. These reactions occur in the presence of catalysts such as (1) enzymes (e.g., alkaline phosphatase, horseradish peroxidase, microperoxidase) and (2) metal ions or metal complexes (e.g., Cu^{2+} and Fe^{3+} phthalocyanine complexes).

Chemiluminescence assays are ultrasensitive (attomole-to-zeptomole detection limits) and have wide dynamic ranges. They are now widely used in automated immunoassay and DNA probe assay systems, such as (1) acridinium ester and acridinium sulfonamide labels, (2) 1,2-dioxetane substrates

for alkaline phosphatase labels, and (3) the enhanced luminol reaction for horseradish peroxidase labels.

Electrochemiluminescence

Electrochemiluminescence differs from chemiluminescence in that the reactive species that produce the chemiluminescent reaction are electrochemically generated from stable precursors at the surface of an electrode. A ruthenium (Ru^{2+}), tris(bipyridyl) chelate is the most commonly used electrochemiluminescence label, and electrochemiluminescence is generated at an electrode via an oxidation reduction type of reaction with tripropylamine. This chelate is very stable and relatively small, and has been used to label haptens or large molecules (e.g., proteins, oligonucleotides). The electrochemiluminescence process has been used in both immunoassays and nucleic acid assays. Advantages of this process include (1) improved reagent stability, (2) simple reagent preparation, and (3) enhanced sensitivity. With its use, detection limits of 200 fmol/L and a dynamic range extending over six orders of magnitude have been obtained.

Instrumentation

The basic components of a luminometer include (1) the sample cell housed in a light-tight chamber, (2) the injection system for adding reagents to the sample cell, and (3) the detector. The detector is usually a PMT. However, a charged coupled detector (a multichannel device), an x-ray film, or photographic film has been used to image chemiluminescence reactions on a membrane or in the wells of a microplate. For electrochemiluminescence, the reaction vessel incorporates an electrode at which the electrochemiluminescence is generated.

Limitations of Chemiluminescence and Electrochemiluminescence Measurements

Factors that commonly degrade the analytical performance of luminescence measurements include (1) light leaks, (2) light piping, (3) and high background luminescence from assay reagents and reaction vessels (e.g., plastic tubes exposed to light). The ultrasensitive nature of chemiluminescence assays requires stringent controls on the purity of reagents and the solvents (e.g., water) used to prepare reagent solutions. Efficient capture of the light emission from reactions that produce a flash of light requires an efficient injector that provides adequate mixing when the triggering reagent is added to the reaction vessel. Chemiluminescence, and electrochemiluminescence assays have a wide linear range, usually including several orders of magnitude, but very high-intensity light emission has led to pulse pileup in PMT tubes, and this may lead to a serious underestimation of the true light emission intensity.

POINTS TO REMEMBER

Radiant Energy in Analytical Measurements

- Fluorescence: light is absorbed by a molecule and subsequently emitted as light at a longer wavelength
- Chemiluminescence: light is emitted as a result of chemical energy; no light is absorbed
- Electrochemiluminescence: light is generated from precursor molecules at the surface of an electrode

NEPHELOMETRY AND TURBIDIMETRY

Light scattering is a physical phenomenon that results from the interaction of light with particles in solution. **Nephelometry** and **turbidimetry** are analytical techniques that are used to measure scattered light. Light-scattering measurements have been applied to immunoassays of specific proteins and haptens.

Basic Concepts

Light scattering occurs when radiant energy passing through a solution encounters a molecule in an elastic collision, which results in scattering of light in all directions. Unlike fluorescence emission, the wavelength of the scattered light is the same as that of the incident light. The principal factors that influence light scattering include the size, concentration and molecular weight of the particles, wavelength, and distance of observation.

Light scattering from small particles is directly proportional to their concentration and molecular weight. Light scatter is inversely proportional to the fourth power of wavelength (blue light scatters more than red light) and inversely proportional to the square of the distance from the light scatter source to the detector. Thus the detector should be located close to the analytical cell by combining the cell and the detector or by using good collection optics.

As the particles become larger than the incident light wave, the radiated light waves are no longer all in phase. Reinforcement of radiation occurs in some directions, and destructive interference occurs in others. The scattering patterns from these large particles are characteristic of the size and shape of the particle.

Measurement of Scattered Light

Turbidimetry and nephelometry are methods used to measure scattered light. These techniques have proved useful for the quantification of serum proteins.

Turbidimetry

Because of light scattering, the intensity of light reaching the detector at 180 degrees is reduced. The measurement of this decrease in intensity is called *turbidimetry*. Analogous to absorption spectroscopy, turbidity is defined as:

$$I = I_0 e^{-bt} \quad (9.7)$$

$$\text{or } t = \left(\frac{1}{b}\right) \ln \left(\frac{I_0}{I}\right) \quad (9.8)$$

where t = turbidity; b = path length of incident light through the solution of light-scattering particles; I = intensity of transmitted light; and I_0 = intensity of incident light.

A turbidimeter is used to measure the intensity of light scattering. Photometers or spectrophotometers are often used as turbidimeters, as turbidimetric measurements are easily performed with them and require little optimization. The principal concern of turbidimetric measurements is signal-to-noise ratio. Photometric systems with electro-optical noise in the range of ± 0.0002 absorbance unit or less are useful for turbidity measurements.

Fig. 9.13 Schematic diagram of light-scattering instrumentation shows (a) the optics position for a turbidimeter, (b) the optics position for a forward-scattering nephelometer, and (c) the optics position for a right-angle nephelometer.

Nephelometry

Nephelometry is defined as the detection of light energy scattered or reflected toward a detector that is not in the direct path of the transmitted light. Common nephelometers measure scattered light at right angles to the incident light. Some nephelometers are designed to measure scattered light at an angle other than 90 degrees to take advantage of the increased forward-scatter intensity caused by light scattering from larger particles (e.g., immune complexes).

Fluorometers are often used to perform nephelometric measurements. However, the angular dependence of light-scattering intensity has resulted in the design of special nephelometers. These devices place the PMT detector at appropriate angles to the excitation light beam. The design principle of a nephelometer is similar to the design principle applied in fluorescence measurements. The major operational difference between the fluorometer and the nephelometer is that the excitation and detection wavelengths of a nephelometer will be set to the same value. The principal parameters of light scatter instrumentation are (1) excitation intensity, (2) wavelength, (3) distance of the detector from the sample cuvet, and (4) minimization of external stray light. As shown in Fig. 9.13, the basic components of a nephelometer include (1) a light source, (2) collimating optics, (3) a sample cell, and (4) collection optics, which include light-scattering optics, a detector optical filter, and a detector. The schematic diagram also shows the different angles from the incident light beam where the detector, filter, and optics are placed to measure light scattering. Fig. 9.13(a) shows the straight-through arrangement for turbidimetry, whereas Fig. 9.13(b and c) shows arrangements frequently found in nephelometers. The detector arrangement shown in Fig. 9.13(b) is used for measurement of forward

scatter at 30 degrees, which is the optical arrangement used in some commercial nephelometers.

Operationally, the optical components used in turbidimeters and nephelometers are similar to those used in fluorometers or photometers. For example, the light sources commonly used are (1) quartz-halogen lamps, (2) xenon lamps, and (3) lasers. Helium-neon (He-Ne) lasers, which operate at 633 nm, have typically been used for light-scattering applications, such as (1) nephelometry (2) immunoassays, (3) particle size determination, and (4) particle shape determination. The laser beam is used specifically in some nephelometers because of its high intensity; in addition, the coherent nature of laser light makes it ideally suited for nephelometric applications. Ratio-referencing fluorometers are also well suited for nephelometric measurements.

Limitations of Light-Scattering Measurements

Antigen excess and matrix effects are limitations encountered in the use of turbidimeters and nephelometers for measurement of analytes of clinical interest.

Antigen Excess

As turbidity increases during the addition of antigen to antibodies, the signal increases to a maximum value and then decreases. The point at which the decrease begins marks the beginning of the phase of antigen excess; this phenomenon is explained in Chapter 15. Consequently, light-scattering methods for quantification of antigen-antibody reactions must provide a method for detecting antigen excess. The kinetics of immune complex formation measured by nephelometry or turbidimetry is sufficiently different in each of the three phases—(1) antibody excess, (2) equivalence, and (3) antigen excess—that computer algorithms can automatically flag antigen excess.

Matrix Effects

Particles, solvents, and all serum macromolecules scatter light. Lipoproteins and chylomicrons in lipemic serum provide the highest background turbidity or nephelometric intensity. When measuring an antigen by light scattering, lipemia within the sample will cause background interference since the lipid molecules will also scatter light. Lipemic samples may continue to have interference upon dilution since the antigen concentration is also decreased. Instead of dilution, rate measurements are a more effective method for minimizing lipemic interference.

POINTS TO REMEMBER

Light Scattering Assays

- Turbidity assays measure light scattering to determine the formation of antigen-antibody complexes
- Interferences in light scattering include:
 - An excess of antigen decreases the turbidity
 - Macromolecules, such as lipoproteins, chylomicrons, and dust in the sample matrix, will increase the background turbidity
- Macromolecule interference in light scattering can be decreased by using rate measurements rather than directly assessing light scattering

REVIEW QUESTIONS

1. What wavelength of light in the electromagnetic spectrum has the highest energy?
 - a. 400 nm
 - b. 500 nm
 - c. 550 nm
 - d. 660 nm
2. The emission of light caused by a chemical reaction is:
 - a. chemiluminescence.
 - b. nephelometry.
 - c. turbidimetry.
 - d. fluorescence.
3. The expression of the relationship between the concentration of a substance in solution and absorbance of light by that substance is referred to as Beer's law. This relationship is expressed in a formula as:
 - a. $\log (1/T)$.
 - b. $C = abc$.
 - c. $I_0/I_s \times 100$.
 - d. $A = abc$.
4. Calculate the concentration of NADH, given that the absorbance at 340 nm is 0.5 and the molar absorptivity constant is $6220 \text{ M}^{-1} \text{ cm}^{-1}$. The cuvet has a path length of 1 cm.
 - a. 1.0 μM
 - b. 10.0 μM
 - c. 0.8 μM
 - d. 8.0 μM
 - e. 0.05 μM
5. Which component of a single-beam spectrophotometer isolates radiant energy of a specific wavelength and excludes that of other wavelengths?
 - a. Monochromator
 - b. Entrance slit
 - c. Cuvet
 - d. Light source
6. Measurement of the concentration of a substance that is performed by measuring scattered light at right angles to the incident light beam is called:
 - a. fluorometry.
 - b. atomic absorption.
 - c. turbidimetry.
 - d. nephelometry.
7. A solution that is identical to that of calibrating or unknown solutions and is used to set 100% T (zero absorbance) at the beginning of a photometric analysis is referred to as a:
 - a. standard solution.
 - b. calibrating solution.
 - c. reference blank.
 - d. reagent blank.
8. Calculate the transmittance of light when the absorbance in a sample is 0.5.
 - a. 25.6%
 - b. 40.1%
 - c. 31.6%
 - d. 10.9%
9. In a flameless atomic absorption technique, the sample holder is typically a:
 - a. carbon rod in an enclosed chamber.
 - b. flame.
 - c. borosilicate glass cuvet.
 - d. reflective surface.
10. The bandwidth of the spectral absorbance curve of an absorbing substance at a point equal to one-half of the maximum absorbance is referred to as the:
 - a. standard curve.
 - b. bandpass filter.
 - c. natural bandwidth.
 - d. monochromatic bandwidth.

Electrochemistry and Chemical Sensors

Paul D'Orazio*

OBJECTIVES

1. Define the following: (a) amperometry, (b) biosensor, (c) conductometry, (d) coulometry, (e) electromotive force, (f) indicator electrode, (g) ion activity, (h) molality, (i) optode, (j) potentiometry, (k) reference electrode, and (l) voltammetry.
2. State the major advantages of electrochemical sensors for whole blood measurements.
3. Describe the components of a basic potentiometric cell and their functions, including electrodes, filling solutions, and voltmeter.
4. State the principle, a clinical application, and a potential interfering substance for each of the following electrochemical measurement techniques: (a) potentiometry, (b) voltammetry/amperometry, (c) conductometry, and (d) coulometry.
5. Describe the fundamental differences between direct potentiometry for measurement of electrolytes in serum, plasma, and whole blood and analytical methods which measure ion concentration.
6. Describe a PCO_2 electrode, including components and internal reactions.
7. Describe a PO_2 electrode, including components and internal reactions.
8. Define a biosensor; describe the two major categories of biosensors and a practical example of each type in the clinical laboratory.
9. Describe four transduction mechanisms used for enzyme-based biosensors and a practical example of each in the clinical laboratory.
10. State the application of the Nernst equation to electrochemical measurements.

KEY WORDS AND DEFINITIONS

Activity (of an ion) The concentration of free, unbound ion in solution.

Amperometry An electrolytic electrochemical process in which current is monitored at a fixed (controlled) voltage between working and reference electrodes in an electrochemical cell.

Biosensor A type of chemical sensor consisting of a biologic recognition element and a physicochemical transducer, often an electrochemical or an optical device.

Conductometry An electrochemical technique used to determine the quantity of an analyte present in a mixture by measuring its effect on the electrical conductivity of the mixture.

Coulometry An electrochemical technique that measures the electrical charge passing between two electrodes in an electrochemical cell, with the amount of charge passing between the electrodes being directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes.

Electrochemical cell A device that consists of two electrodes (electron or metallic conductors) connected by an electrolyte solution that conducts ions (galvanic cell), or a device in which an external voltage is applied to a polarizable working electrode versus a reference electrode, with the resulting cathodic or anodic current of the cell being monitored (electrolytic cell).

Electrode A half-cell that consists of a single metallic conductor in contact with an electrolyte solution; the indicator (measuring) electrode is one half-cell and the reference electrode is the second half-cell.

Electrode potential The electromotive force (EMF) of a single half-cell measured with respect to the standard hydrogen electrode, set at zero by convention.

Ion-selective electrode An electrode that selectively interacts with a single ionic species; the potential produced at the membrane/sample solution interface is proportional to the logarithm of the ionic activity or the concentration of the ion in question.

*The author gratefully acknowledges the contributions of Drs. Richard A. Durst, Ole Siggaard-Andersen, and Mark E. Meyerhoff to earlier versions of this chapter.

Nernst equation The equation used to relate the potential of an electrochemical cell to the activity of a chemical species in solution.

Optode An optical sensor that measures specific substances such as pH, blood gases, and electrolytes, using dye immobilization, fluorescence quenching, or phosphorescence.

Potential difference The work required to move an electrical charge and measured in volts.

Potentiometry An electrochemical technique that measures an electrical potential difference between two electrodes (half-cells) in an electrochemical cell.

Redox couple A conjugate pair of substances that consists of any substance that accepts electrons (the oxidant) and any substance that donates electrons (the reductant); redox processes take place only between two redox couples, with electrons transferred from a reductant (Red_1) to an oxidant (Ox_2).

Voltammetry An electrolytic process in which a specific oxidation or reduction reaction occurs at the surface of the working electrode in response to an applied potential. The charge transfer at this interface (current flow) provides analytical information.

Electrochemical measurements are key analytical methods used especially in critical care clinical laboratories. In this chapter the fundamental electrochemical sensing principles of (1) potentiometry, (2) voltammetry/ampereometry, (3) conductometry, and (4) coulometry will be summarized and clinical applications presented. Chemical sensors based on optical measurements and biosensors, both biocatalytic and affinity based, will be introduced and practical examples will be presented.

POTENTIOMETRY

Potentiometry is used clinically for measurement of pH, PCO_2 , and electrolytes (Na^+ , K^+ , Cl^- , Ca^{2+} , Mg^{2+} , Li^+) in whole blood, serum, plasma, and urine and as the basis for some biosensors for metabolites of clinical interest.

Basic Concepts

Potentiometry is the measurement of an electrical **potential difference** between two **electrodes** (half-cells) in an **electrochemical cell** when the cell current is zero (Fig. 10.1). Such a cell consists of two electrodes, known as the indicator (measuring) and the reference electrodes, shown in Fig. 10.1 on the left and right, respectively. The two electrodes are connected by an electrolyte solution (sample). Each half-cell consists of an internal silver–silver chloride (Ag/AgCl) electrode, which is a specific type of potentiometric electrode known as a redox electrode. Each Ag/AgCl electrode is in contact with an internal electrolyte. The indicator electrode, also known as an **ion-selective electrode** (ISE), contains an inner electrolyte with a constant **activity** of the ion of interest in the form of a chloride salt. The reference electrode contains a high concentration of electrolyte, usually potassium chloride.

The electromotive force (E or EMF) is defined as the maximum difference in potential between the two electrodes when the cell current is zero. The cell potential is measured using a voltmeter, of which the common pH meter is a special type. To obtain an accurate potential measurement, it is necessary that no current flows through the cell. This is accomplished by incorporating a high input impedance of greater than $10^{12} \Omega$ within the voltmeter.

The overall potential of a potentiometric cell is the sum of all potential gradients that exist between different phases of

the cell. The potential of a single electrode with respect to the surrounding electrolyte and the absolute magnitude of the individual potential gradients between phases are unknown and cannot be measured. Only potential differences between two electrodes (half-cells) can be measured. Potential gradients can be classified as (1) redox potentials, (2) membrane potentials, or (3) diffusion potentials. In general, it is possible to devise a cell in such a manner that all potential gradients except one are constant. This potential then can be related to the activity of a specific ion of interest (e.g., hydrogen $[\text{H}^+]$ or Na^+).

Types of Electrodes

Different types of electrodes are used for potentiometric applications. They include (1) redox, (2) ion-selective membrane (glass and polymer), and (3) PCO_2 gas-sensing electrodes.

Redox Electrodes

Redox potentials are the result of chemical equilibria involving electron transfer reactions:

where n = the number of electrons involved in the reaction. Any substance that accepts electrons is an oxidant (Ox), and

Fig. 10.1 Schematic of ion-selective membrane electrode-based potentiometric cell. Ag/AgCl , Silver–silver chloride; KCl , potassium chloride.

any substance that donates electrons is a reductant (Red). The two forms, Ox and Red, represent a **redox couple** (conjugate redox pair). Usually, homogeneous redox processes take place only between two redox couples. In such cases, electrons are transferred from Red₁ to an Ox₂. In this process, Red₁ is oxidized to its conjugate Ox₁, whereas Ox₂ is reduced to Red₂:

The **electrode potential** for a redox couple is defined as the couple's potential measured with respect to the standard hydrogen (H₂) electrode, which by convention is set equal to zero. In such a cell, the standard H₂ electrode is the reference electrode and the given half-cell is the indicator electrode. The potential for the redox couple is shown by the **Nernst equation**:

$$E = E^0 - \frac{N}{n} \times \log \frac{a_{\text{Red}}}{a_{\text{Ox}}} = E^0 - \frac{0.0592 \text{ V}}{n} \times \log \frac{a_{\text{Red}}}{a_{\text{Ox}}} \quad (10.3)$$

where E = electrode potential of the cell; E^0 = standard electrode potential when $a_{\text{Red}}/a_{\text{Ox}} = 1$; n = number of electrons involved in the redox reaction; $N = (R \times T \times \ln 10)/F$ (the Nernst factor if $n = 1$); $N = 0.0592 \text{ V}$ if $T = 298.15 \text{ K}$ (25°C); $N = 0.0615 \text{ V}$ if $T = 310.15 \text{ K}$ (37°C); R = gas constant ($8.31431 \text{ Joule} \times \text{K}^{-1} \times \text{mol}^{-1}$); T = absolute temperature (in kelvins); F = faraday constant ($96,487 \text{ coulombs} \times \text{mol}^{-1}$); $\ln 10$ = natural logarithm of 10 = 2.303; a = activity; and $a_{\text{Red}}/a_{\text{Ox}}$ = product of mass action for the redox reaction.

Redox electrodes currently in use include (1) inert metal electrodes immersed in solutions containing redox couples and (2) metal electrodes whose metal functions as a member of the redox couple.

Inert Metal Electrodes

Platinum and gold (Au) are examples of inert metals used to monitor the potential of a redox couple in a background electrolyte. The H₂ electrode is a special redox electrode for pH measurement. It consists of a Pt or Au electrode that is electrolytically coated (platinized) with highly porous Pt (Pt black) to catalyze the electrode reaction:

The electrode potential is given by:

$$E = E^0 - N \times \log \frac{(f_{\text{H}_2})^{1/2}}{f_{\text{H}_2} a_{\text{H}^+}} \quad (10.5)$$

or

$$E = E^0 - N \times \left[\log (f_{\text{H}_2})^{1/2} - \log a_{\text{H}^+} \right] \quad (10.6)$$

where $E^0 = 0$ at all temperatures (by convention); f_{H_2} = fugacity of H₂ gas (the "effective" partial pressure of a gas under ideal conditions); a_{H^+} = activity of H⁺ ions; and $-\log a_{\text{H}^+}$ = negative log of H⁺ activity (p_{aH^+} or pH).

When fugacity H₂ (f_{H_2}) in the solution is maintained constant by bubbling H₂, the potential is a linear function

of $\log a_{\text{H}^+}$ ($= -\text{pH}$). In the standard H₂ electrode, the electrolyte consists of an aqueous solution of HCl with activity of HCl equal to 1.000 (concentration of HCl = 1.2 mol/L) in equilibrium with a gas phase, and with f_{H_2} equal to 1.000 ($P_{\text{H}_2} = 101.3 \text{ kPa} = 1 \text{ atm}$). The standard H₂ electrode is also used as a reference electrode.

Metal Electrodes Participating in Redox Reactions

The Ag/AgCl electrode is an example of a metal electrode that participates as a member of a redox couple. The Ag/AgCl electrode consists of an Ag wire or rod coated with AgCl_(solid) in contact with a Cl[−] solution of constant activity; this sets the half-cell potential. The Ag/AgCl electrode is itself considered a potentiometric electrode because its phase boundary potential is governed by an oxidation-reduction electron transfer equilibrium reaction that occurs at the surface of Ag:

The Nernst equation for the reference half-cell potential of an Ag/AgCl reference electrode is written as follows:

$$E_{\text{Ag/AgCl}} = E_{\text{Ag/AgCl}}^0 + \frac{RT}{nF} \times \ln \frac{a_{\text{AgCl}}}{a_{\text{Ag}} a_{\text{Cl}^-}} \quad (10.8)$$

Because AgCl and Ag are both solids, their activities are equal to unity ($a_{\text{AgCl}} = a_{\text{Ag}}^0 = 1$). Therefore, from Eq. 10.8, the half-cell potential is controlled by the activity of the Cl[−] ion in solution (a_{Cl^-}) contacting the electrode.

The Ag/AgCl electrode is used both as an internal reference element in potentiometric ISEs and as an external reference electrode half-cell of constant potential, which is required to complete a potentiometric cell (see Fig. 10.1). In both cases the Ag/AgCl electrode must be in equilibrium with a solution of constant Cl[−] ion activity.

The Ag/AgCl element of the reference electrode half-cell is in contact with a high-concentration solution of a soluble Cl[−] salt. Saturated KCl is commonly used. A porous membrane or frit is frequently used to separate the concentrated KCl from the sample solution. The frit serves both as a mechanical barrier to hold the concentrated electrolyte within the electrode and as a diffusional barrier to prevent proteins and other species in the sample from coming into contact with the internal Ag/AgCl element, which could poison and alter its potential. The interface between two dissimilar electrolytes (concentrated KCl/calibrator or sample) occurs within the frit and develops the liquid-liquid junction potential (E_j), a source of error in potentiometric measurements. The difference in E_j between calibrator and sample (residual liquid junction potential) is responsible for this error and can be minimized and usually neglected in practice if the compositions of the calibrating solutions are matched as closely as possible to the sample with respect to ionic content and ionic strength. A reference electrolyte at high concentration, with equal cation and anion mobility, further helps to minimize the residual liquid junction potential. KCl at a concentration 2 mol/L or more is preferred. Differences of approximately −2% in the measurement of sodium by ISEs have been demonstrated

when the KCl concentration in the reference electrolyte is lowered from 3 to 0.5 mol/L.

The presence of erythrocytes in the sample may affect the magnitude of the residual liquid junction potential in a less predictable manner. For example, erythrocytes in a blood sample with a normal hematocrit are estimated to produce approximately 1.8 mmol/L positive error in the measurement of Na⁺ by ISEs when an open, unrestricted liquid-liquid junction is used. This bias may be minimized if a restrictive membrane or frit is used to modify the liquid-liquid junction.

ION-SELECTIVE MEMBRANE ELECTRODES

Membrane potentials are produced by permeability of certain types of membranes to selected anions or cations. Such membranes are used to fabricate ISEs that selectively interact with a single ionic species. The potential produced at the membrane-sample solution interface is proportional to the logarithm of the ionic activity or concentration of the ion in question. Measurements with ISEs are simple, rapid, nondestructive, capable of being used directly in a turbid matrix such as whole blood and applicable to a wide range of concentrations.

The ion-selective membrane controls the selectivity of the electrode. Ion-selective membranes are typically composed of glass, crystalline, or polymeric materials. The chemical composition of the membrane is designed to achieve an optimal permselectivity toward the ion of interest. In practice, other ions exhibit finite interaction with membrane sites and display some degree of interference for determination of an analyte ion. In clinical practice, if the interference exceeds an acceptable quantity, a correction is required.

The selectivity of an ISE for the ion of interest over interfering ions is:

$$E = E^0 + \left[\frac{2.303 RT}{z_i F} \right] \log \left(a_i + \sum K_{ij} a_j^{z_i/z_j} \right) \quad (10.9)$$

where a_i = activity of the ion of interest; a_j = activity of the interfering ion; and K_{ij} = selectivity coefficient for the primary ion over the interfering ion. Low values indicate good selectivity for the analyte i over the interfering ion j ; z_i = charge of the primary ion; and z_j = charge of the interfering ion. All other terms are identical to those in the Nernst equation (Eq. 10.3).

Various approaches may be used to determine the selectivity of an ISE for a primary ion over an interfering ion. A straightforward approach is the separate solution method, in which the potential of an ISE is determined in solutions of the primary and interfering ions separately, at equal ionic activities. The selectivity coefficient is then calculated as follows:

$$\log K_{ij} = \frac{E_j - E_i}{\frac{2.303 RT}{nF}} + \left(1 - \frac{z_i}{z_j} \right) \log a_i \quad (10.10)$$

An alternate approach to determine the selectivity coefficient is the fixed interference method, in which the potential response of an ISE to the primary ion is determined in

TABLE 10.1 Required Selectivities for Cation-Selective Ion-Selective Electrodes for Whole Blood, Plasma, and Serum Measurements

Primary Ion (I)	Required Selectivity Coefficient (log K_{ij})					
	Interfering Cation (J)					
	H ⁺	Li ⁺	Na ⁺	K ⁺	Mg ²⁺	Ca ²⁺
H ⁺	—	−6.5	−8.5	−7.0	−7.7	−7.7
Li ⁺ ^a	2.1	—	−4.3	−2.8	−3.5	−3.6
Na ⁺	4.4	−0.1	—	−0.6	−1.2	−1.3
K ⁺	2.8	−1.7	−3.6	—	−2.8	−2.9
Mg ²⁺	8.9	0.1	−3.9	−0.9	—	−2.4
Ca ²⁺	9.3	0.4	−3.6	−0.6	−1.9	—

^aAssumes a therapeutic range for Li⁺ between 0.7 and 1.5 mmol/L. Ca²⁺, ionized calcium; H⁺, hydrogen; K⁺, potassium; Li⁺, lithium; Mg²⁺, magnesium; Na⁺, sodium.

solutions of constant activity of the interfering ion. The potential values obtained are plotted versus the logarithm of the activity of the primary ion a_i . The intersection of the extrapolation of the linear portions of this plot indicates the value of a_i to be used to calculate K_{ij} :

$$K_{ij} = a_i / a_j^{z_i/z_j} \quad (10.11)$$

where all terms have the same definition as in Eq. 10.9. Traditionally the fixed interference method has been preferred because it more closely resembles a practical application of the sensor, in that primary and interfering ions are present simultaneously in solution and must compete for complexation sites in the ISE membrane.

Most ISEs used in clinical practice have sufficient selectivity and do not require correction for interfering ions. Table 10.1 shows required selectivity coefficients for the measurement of cations of interest in clinical chemistry over potentially interfering cations, assuming an acceptable maximum interference of 1% for the ion of interest.

Glass membrane and polymer membrane electrodes are two types of ISEs that are commonly used in clinical chemistry.

Glass Electrode

Glass membrane electrodes are used to measure pH and Na⁺ and as an internal H⁺ selective transducer for PCO₂ sensors. Glass electrode membranes are formulated from melts of silicon and/or aluminum oxide (Al₂O₃) mixed with oxides of alkaline earth or alkali metal cations. By varying the glass composition, electrodes with selectivity for H⁺, Na⁺, K⁺, Li⁺, rubidium (Rb⁺), cesium (Cs⁺), Ag⁺, thallium (Tl⁺), and ammonium (NH₄⁺) have been demonstrated. However, glass electrodes for H⁺ and Na⁺ are currently the only types with sufficient selectivity over interfering ions to allow practical application in clinical chemistry. A typical formulation for H⁺ selective glass is 72% silicon dioxide (SiO₂), 22% Na₂O, and 6% calcium oxide (CaO), which has a selectivity order of H⁺ >>> Na⁺ > K⁺. This glass membrane has sufficient selectivity for H⁺ over Na⁺ to allow error-free measurements of

pH in the range of 7.0 to 8.0 ($[H^+] = 10^{-7}$ to 10^{-8} mol/L) in the presence of greater than 0.1 mol/L Na^+ . Glass pH electrodes with selectivity coefficients ($K_{H/Na}$) over Na^+ of 10^{-7} and better have been realized. By altering the formulation of the glass membrane slightly to 71% SiO_2 , 11% Na_2O , and 18% Al_2O_3 , its selectivity order becomes $H^+ > Na^+ > K^+$. Thus the preference of the glass membrane for H^+ over Na^+ is greatly reduced, resulting in a practical sensor for Na^+ at pH values typically found in blood.

Polymer Membrane Electrodes

Polymer membrane ISEs are used for monitoring pH and for measuring electrolytes, including K^+ , Na^+ , Cl^- , Ca^{2+} , Li^+ , Mg^{2+} , and carbonate (CO_3^{2-}) (for total CO_2 measurements). They are the predominant class of potentiometric electrodes used in clinical analysis instruments.

Response mechanisms of polymer membrane ISEs fall into three categories: (1) charged, dissociated ion exchanger; (2) charged associated carrier; and (3) neutral ion carrier (ionophore).

1. For charged, dissociated ion exchangers, selectivity is not controlled by any specific interaction between a ligand in the polymer membrane and an ion in solution but by extraction of ions into the membrane based on their lipophilic character. For example, dissociated anion exchanger-based electrodes using lipophilic quaternary ammonium salts as active membrane components are used commercially for the determination of Cl^- in whole blood, serum, and plasma, despite some limitations. Selectivity for this type of ISE is controlled by extraction of the ion into the organic membrane phase and is a function of the lipophilic character of the ion because no direct binding interaction occurs between the exchanger site and the anion in the membrane phase. Thus the selectivity order for a Cl^- ISE based on an anion exchanger is fixed as lipophilic anion $R^- > perchlorate (ClO_4^-) > iodide (I^-) > nitrate (NO_3^-) > bromide (Br^-) > Cl^- > fluoride (F^-)$, where R^- represents anions with greater lipophilic character than ClO_4^- . Application of the Cl^- ion-exchange electrode is therefore limited to samples without significant concentrations of anions more lipophilic than Cl^- . For example, blood samples containing salicylate or thiocyanate will produce positive interference for the measurement of Cl^- . Repeated exposure of the electrode to the anticoagulant heparin will lead to loss of electrode sensitivity toward Cl^- because of the extraction of negatively charged heparin into the membrane.
2. For charged, associated carriers, there is specific ion exchange or complexation between the carrier in the polymer membrane and an ion in solution. An early charged-associated, ion-exchanger type ISE for Ca^{2+} was developed and commercialized for clinical application in the 1960s based on the Ca^{2+} -selective, ion-exchange/complexation properties of 2-ethylhexyl phosphoric acid dissolved in dioctyl phenyl phosphonate. A porous membrane was impregnated with this cocktail and mounted at the end of an electrode body. This type of sensor was referred to as the "liquid membrane" ISE. Later, a method was devised in which these ingredients

Fig. 10.2 Typical electromotive force response of potassium (K^+) selective membrane electrode to changes in activity of K^+ in the sample solution. Bracketed interval represents the normal reference interval of K^+ concentration in blood. $Ag/AgCl$, Silver-silver chloride. (From D'Orazio, P. [2002]. In K. Lewendrowski [Ed.]. *Clinical chemistry: laboratory management and clinical correlations* [p. 455]. Philadelphia: Lippincott, Williams and Wilkins.)

could be cast into a plasticized poly(vinyl chloride) (PVC) membrane that was more rugged and convenient to use.

3. For neutral ion carriers (ionophores), the ionophore molecule in the polymer membrane can reversibly and selectively complex an ion of interest in the sample. The interaction is not based on charge, but rather the ion is accommodated based primarily on size within a cavity in the structure of the molecule. A breakthrough in the development and routine application of PVC-type ISEs was the discovery that the neutral antibiotic valinomycin could be incorporated into organic liquid membranes (and later plasticized PVC membranes), resulting in a sensor with high selectivity for K^+ over Na^+ ($K_{K/Na} = 2.5 \times 10^{-4}$). The K^+ ISE based on valinomycin was the first example of a neutral carrier ISE and is now used extensively for the routine measurement of K^+ in blood. Fig. 10.2 shows the response of the valinomycin-based K^+ ISE in the presence of physiologic concentrations of Na^+ , Ca^{2+} , and Mg^{2+} . The wide linear range and excellent selectivity of this ISE over three orders of magnitude makes it suitable for the measurement of K^+ in blood and urine. The K^+ range in blood is only a small portion of the electrode linear range and is spanned by a total ΔEMF of approximately 9 mV. Interference from other cations, which is seen as deviation from linearity, is not apparent at K^+ activities more than 10^{-4} mol/L. Other, less selective polymer-based ISEs based on neutral carriers (e.g., for the measurement of Mg^{2+} and Li^+) are subject to interference from Ca^{2+}/Na^+ and Na^+ , respectively, requiring simultaneous determination and correction for the presence of significant concentrations of these interfering ions. Studies regarding the relationship between molecular structure and ionic selectivity have resulted in the development of polymer-based ISEs using many naturally occurring and synthetic ionophores, with sufficient selectivity for application in clinical analysis. The chemical structures of several of these neutral ionophores are illustrated in Fig. 10.3.

Fig. 10.3 Structures of common ionophores used to fabricate polymer membrane-type ion-selective electrodes for clinical analysis.

Fig. 10.4 Partial pressure of carbon dioxide sensor used to monitor carbon dioxide (CO_2) concentrations in blood samples. Ag/AgCl , Silver–silver chloride. (From Siggard-Andersen, O. [1974]. *The acid-base status of the blood* [4th ed., p. 172]. Baltimore, MD: Williams & Wilkins.)

High selectivity for the CO_3^{2-} anion can be achieved using a neutral carrier ionophore that possesses trifluoroacetophenone groups doped within a polymeric membrane. Such ionophores form negatively charged adducts with CO_3^{2-} anions, and the resulting electrodes have proven useful in commercial instruments for determination of total CO_2 in serum or plasma, after dilution of the sample to a pH value in the range of 8.5 to 9.0, where a significant fraction of total CO_2 exists as CO_3^{2-} .

Electrodes for Partial Pressure of Carbon Dioxide

Electrodes have been developed to measure PCO_2 in body fluids. The first PCO_2 electrode, developed in the 1950s, used a glass pH electrode as the internal element in a potentiometric cell. This important development paved the way for commercial availability of the three-channel blood analyzer (pH, PCO_2 , PO_2) providing a complete picture of oxygenation and acid-base status of blood.

Fig. 10.4 shows a diagram of a typical electrode for PCO_2 . A thin membrane (approximately 20 μm), permeable only to gases and water vapor, is in contact with the sample. Membranes of silicone rubber, Teflon, and other polymeric materials are suitable for this purpose. On the opposite side of the membrane is a thin electrolyte layer consisting of a weak bicarbonate salt (approximately 5 mmol/L) and a Cl^- salt. A pH electrode and an Ag/AgCl reference electrode are in contact with this solution. The PCO_2 electrode is a self-contained

potentiometric cell. CO_2 gas from the sample or calibration matrix diffuses through the membrane and dissolves in the internal electrolyte layer. Carbonic acid is formed and dissociates, shifting the pH of the bicarbonate solution in the internal layer as follows:

and

$$\Delta \log \text{PCO}_{2(\text{sample})} \approx \Delta \text{pH}_{(\text{internal layer})} \quad (10.13)$$

The relationship between the sample PCO_2 and the signal generated by the internal pH electrode is logarithmic and is governed by the Nernst equation. The electrode may be calibrated using precision gas mixtures or using solutions with stable PCO_2 concentrations. Although this style of electrode for PCO_2 has gained widespread use in modern blood gas analyzers, the format in which such sensors may be constructed is limited by size, shape, and the ability to fabricate the internal pH sensitive element.

A slightly different potentiometric cell for PCO_2 is shown in Fig. 10.5. This cell arrangement uses two PVC-type, pH-selective electrodes in a differential mode. The electrode membranes contain tridodecylamine neutral ionophore exhibiting high selectivity for H^+ (see Fig. 10.3). One electrode has an internal layer that is buffered, and the other is unbuffered, consisting of a low concentration of bicarbonate salt. CO_2 gas from the sample or calibration matrix diffuses across the

Fig. 10.5 Differential planar partial pressure of carbon dioxide potentiometric sensor design, based on two identical polymeric membrane pH electrodes, but with different internal reference electrolyte solutions. Both pH sensing membranes are prepared with a hydrogen (H^+)-selective ionophore. $Ag/AgCl$, Silver-silver chloride; PVC, poly(vinyl chloride).

outer H^+ -selective PVC membranes of both sensors. On the unbuffered side, CO_2 diffusion produces a potential shift at the internal interface of the pH-responsive membrane proportional to the sample PCO_2 concentration. The signal at the electrode with the buffered internal layer is unaffected by the CO_2 that diffuses across the membrane. Consequently, one half of the sensor responds to pH alone, and the other half responds to both pH and PCO_2 . The signal difference between the two electrodes cancels any contribution of sample pH to the overall measured cell potential. The differential signal is proportional only to PCO_2 . Unlike the prior electrode, this differential potentiometric cell PCO_2 sensor has been commercialized in a planar format and is more easily adaptable to mass production in sensor arrays.

Direct Potentiometry by Ion-Selective Electrodes: Units of Measure and Reporting for Clinical Applications

Older analytical methods such as flame photometry for the measurement of electrolytes provide the total concentration (c) of a given ion in the sample, usually expressed in units of millimoles of ion per liter of sample. Molality (m) is a measure of the moles of ion per mass of water (millimoles per kilogram) in the sample. Using the Na^+ ion as an example, the relationship between concentration and molality is given by

$$c_{Na^+} = m_{Na^+} \times \rho_{H_2O} \quad (10.14)$$

where ρ_{H_2O} = mass concentration of water in kilograms per liter. For normal blood plasma, the mass concentration of water is approximately 0.93 kg/L, but in specimens with increased lipids or protein, the value may be as low as 0.8 kg/L. In these specimens the difference between concentration and molality may be as great as 20%. A significant advantage of direct potentiometry by ISE for the measurement of electrolytes is that the technique is sensitive to molality and therefore is not affected by variations in the concentration of protein or lipids in the sample. Techniques such as flame photometry, ISE methods that require sample dilution (indirect potentiometry), and other photometric methods requiring sample dilution are affected by the presence of protein

and lipids. In these methods, only the water phase of the sample is diluted, which produces results lower than molality as a function of the concentration of protein and lipids in the sample. Thus there is a risk for error, such as a falsely low Na^+ concentration (pseudohyponatremia), in cases of extremely increased protein and lipid concentrations (see also Chapter 24).

In addition to the difference between molality and concentration, measurement of ions by direct potentiometry provides yet another unit of measurement known as activity (a), the concentration of free, unbound ion in solution. Unlike methods sensitive to ion concentration, ISEs do not sense the presence of complexed or electrostatically “hindered” ions in the sample. The relationship between activity and concentration, using Na^+ ion as an example, is expressed as

$$a_{Na^+} = \gamma_{Na^+} \times c_{Na^+} \quad (10.15)$$

where γ = dimensionless quantity known as the activity coefficient. The activity coefficient is primarily dependent on ionic strength of the sample as described by the Debye-Hückel equation:

$$\log \gamma = - \frac{(A \times z^2 \times I^{0.5})}{1 + B \times a \times I^{0.5}} \quad (10.16)$$

where A and B = temperature-dependent constants ($A = 0.5213$ and $B = 3.305$ in water at $37^\circ C$); a = ion size parameter for a specific ion; and I = ionic strength ($I = 0.5 \sum c \times z^2$, where z is the charge number of the ions). Eq. 10.16 shows that a decrease in the activity coefficient occurs with an increase in ionic strength. This effect is more pronounced when the charge (z) of the ion is higher. Activity coefficients for ions in biologic fluids, such as blood and serum, are difficult to calculate with accuracy because of the uncertain contribution of macromolecular ions, such as proteins, to the overall ionic strength. However, assuming that the normal ionic strength of blood plasma is 0.160 mol/kg, estimates of activity coefficients at $37^\circ C$ are as follows: $Na^+ = 0.75$, $K^+ = 0.74$, and $Ca^{2+} = 0.31$. Referring to Eq. 10.15, activity and concentration will differ greatly in samples of physiologic ionic strength, especially for divalent ions.

Physiologically, ionic activity is assumed to be more relevant than concentration when chemical equilibria or biologic processes are considered. Practically, however, ionic concentration is the more familiar term in clinical practice, forming the basis of reference intervals and medical decision concentrations for electrolytes. Early in the evolution of ISEs as practical tools in clinical chemistry, it was decided that changing clinical reference intervals to a system based on activity instead of concentration was impractical and carried risk for clinical misinterpretation. A pragmatic approach for using ISEs in modern analyzers without changing established concentration-based reference intervals is to formulate calibration solutions with ionic strengths and ionic compositions as close as possible to those of blood plasma. In this way, the activity coefficient of each ion in the calibrating solutions approximates that in the sample matrix, allowing calibration and measurement of electrolytes in units of concentration instead of activity.

TABLE 10.2 Examples of Two-Value Calibrating Solutions for Measurement of pH and Electrolytes by Direct Potentiometry

Analyte	Calibration Point (mmol/L)	Slope Point (mmol/L)	Expected Signal Δ , (mV)
Na ⁺	140	110	6.6
K ⁺	4.0	8.0	18
Ca ²⁺	1.25	2.50	9
Cl ⁻	100	80	6
pH	7.38 (pH units)	6.84 (pH units)	32.4

Ionic strength adjusted to 160 mmol/kg with buffer salts and inert electrolytes.

Ca²⁺, Ionized calcium; Cl⁻, chloride; K⁺, potassium; Na⁺, sodium.

A typical set of solutions for multi-ISE calibration in an analyzer is shown in Table 10.2. Two points may be used to calibrate each ISE. The difference in the cell potential generated by these two solutions (ΔE) is used to calculate the response slope of the cell (slope = $\Delta E / \Delta \log c$), where c is the concentration of ion in each calibrating solution, substituted for activity. The standard electrode potential, E^0 , is calculated as the y -intercept. Determination of the ion concentration in an unknown sample is then a straightforward solution of Eq. 10.9 after the cell potential generated by the sample is measured. The measured slope is used in place of the $2.303RT/z_iF$ term of Eq. 10.9. In the absence of significant influence from interfering ions on measurement of the primary ion (e.g., $\leq 1\%$ interference on the measured value), contributions from a_j in Eq. 10.9 may be ignored.

Calibration of the cell is done in units of concentration; however, as mentioned earlier, direct potentiometry is sensitive to the molality of the ion, which is related to concentration by the water content of the sample (Eq. 10.14). The water content of the aqueous calibrating solutions shown in Table 10.2 is approximately 0.99 kg/L. The water content of normal blood plasma is approximately 0.93 kg/L. Molality is 7% greater than the concentration in this normal plasma specimen. The direct potentiometric cell will report results approximately 6% greater than the concentration in normal specimens because of this difference in water content between sample and the calibrator ($0.99/0.93 = 1.06$). Direct potentiometry presents an advantage in that the technique is not affected by the presence of protein and lipids in the sample; however, the application of clinical reference intervals based on concentration again poses a risk for confusion and clinical misinterpretation. Most manufacturers of electrolyte measurement systems have overcome this problem in a practical way by following Clinical and Laboratory Standards Institute (CLSI) guidelines that recommend the use of correlation factors to standardize ISE measurements to units of concentration. These factors may be obtained by standardizing the ISE measurement to certified reference materials based on human serum, with electrolyte values assigned in units of concentration. Appropriate correlation factors are then applied to sample calculations using algorithms resident in the instrument software.

POINTS TO REMEMBER

Advantages of Electrochemical Sensors for Whole Blood Measurements

- Electrochemical sensors measure the most important critical care analytes (gases, electrolytes, glucose) directly in whole blood without need for sample pretreatment or dilution.
- Measurement is rapid and nondestructive.
- Measurement is not affected by sample turbidity (red cells, lipids); only the analyte present in the water phase of plasma is measured.
- Simultaneous measurement of multiple analytes in the same blood sample is possible.

VOLTAMMETRY AND AMPEROMETRY

Voltammetric and amperometric techniques are among the most sensitive and widely applicable of all electroanalytical methods.

Basic Concepts

In contrast to potentiometry, voltammetric, and amperometric methods are based on electrolytic electrochemical cells in which an external voltage is applied to a polarizable working electrode versus a reference electrode and the resulting cathodic (for analytical reductions) or anodic (for analytical oxidations) measured current is proportional to the concentration of the analyte present in the sample. Current flows only if E_{appl} is greater than a certain voltage (decomposition voltage) determined by the thermodynamics for a given redox reaction of interest ($\text{Ox} + ne^- \rightarrow \text{Red}$, which is defined by the E^0 value for that reaction [standard reduction potential]) and the kinetics for heterogeneous electron transfer at the interface of the working electrode. Often, slow kinetics of electron transfer for the redox reaction on a given inert working electrode (Pt, carbon, Au, etc.) mandates use of a much more negative (for reductions) or positive (for oxidations) E_{appl} than predicted based on the E^0 for the redox reaction. This is called an overpotential (η). Regardless of whether an overpotential for electron transfer exists, a specific oxidation or reduction reaction occurs at the surface of the working electrode in voltammetry and/or amperometry, and it is the charge transfer at this interface (current flow) that provides the analytical information.

For electrolytic cells that form the basis of voltammetric and amperometric methods:

$$E_{\text{appl}} = E_{\text{cell}} + \eta - iR_{\text{cell}} \quad (10.17)$$

where E_{cell} = thermodynamic potential between the working and reference electrodes in the absence of an applied external voltage. When the external voltage is greater or less than this equilibrium potential, plus or minus any overpotential (η), current will flow because of an oxidation or reduction reaction at the working electrode. A voltammogram is simply the plot of observed current, i , versus E_{appl} (Fig. 10.6). In **amperometry** (see later), a fixed voltage is applied, and the resulting current is monitored. The amount of current is inversely related to the resistance of the

Fig. 10.6 Current versus voltage curve (voltammogram) obtained for oxidized species that were reduced at the surface of the working electrode, as the E_{appl} is scanned more negatively and the solution is stirred to yield a steady-state response. Decomposition potential is the applied potential where the oxidation or reduction reaction begins. Limiting current is the signal at steady state for the oxidation or reduction reaction and is proportional to concentration of the analyte of interest. E_{appl} , Applied voltage; E_w , potential at the working electrode; E_{ref} , potential at the reference electrode.

Fig. 10.7 Concept of electrochemical reaction increasing diffusion layer thickness (concentration polarization) of analytes via reduction or oxidation (Ox) at the surface of the working electrode. As time increases ($t_1, t_2, t_3, \dots$), the diffusion layer thickness at the surface of the working electrode (δ) grows quickly to a value determined by the degree of convection in the sample solution. $C_{\text{Ox}}^{\text{bulk}}$ and $C_{\text{Ox}}^{\text{surface}}$ are concentrations of oxidizable species in bulk solution and at the surface of the working electrode, respectively.

electrolyte solution and to any “apparent” resistance that develops because of mass transfer of the analyte species to the surface of the working electrode. Because electrochemical reactions are heterogeneous, occurring only at the surface of the working electrode, the amount of current observed is also dependent on the surface area (A) of the working electrode.

When a potential is applied to a working electrode that will oxidize or reduce a species in the solution phase contacting the electrode, the electrochemical reaction causes the concentration of electroactive species to decrease at the surface of the electrode (Fig. 10.7), a process termed concentration polarization. In turn, this causes a concentration gradient of analyte species between the bulk sample solution and

the surface of the electrode. When the bulk solution is stirred, the diffusion layer of the analyte grows out from the surface of the electrode quickly to a fixed distance, which is controlled by how vigorously the solution is stirred. This diffusion layer is termed the Nernst layer and has a finite thickness (δ) after a relatively short time period when the solution is moving (convection). Voltammetry carried out in the presence of convection (by stirring the solution, rotating the electrode, flowing solution by the electrode, and so on) is called steady-state voltammetry. When the solution is not moving, the diffusion layer grows further and further with time (i.e., not constant), creating larger and larger δ values over time. This is termed non-steady-state voltammetry and often results in peak currents in i versus E_{appl} plots for electrolytic cells.

In steady-state voltammetry, when the potential of the working electrode is scanned past a value that will cause an electrochemical reaction, the current will rise rapidly and then will plateau, even as E_{appl} changes further. Fig. 10.6 illustrates such a wave for a hypothetical reduction of an oxidized species (Ox) via an n electron reduction to a reduced species (Red). When the applied potential is much more negative than required, the current reaches a limiting value (termed the limiting current, i_l). This limiting current is proportional to the concentration of the electroactive species (Ox in this case) as expressed by the following equation:

$$i_l = nFA \left(\frac{D}{\delta} \right) c_{\text{Ox}} \quad (10.18)$$

where i = measured current in amperes; n = the number of electrons in the electrochemical reaction (reduction in this case); F = Faraday constant (96,487 coulombs/mol); A = electrochemical surface area of the working electrode (in square centimeters, assuming a planar electrode geometry); D = diffusion coefficient (in square centimeters per second) of the electroactive species (Ox in this case); δ = diffusion layer thickness (in centimeters); and c = concentration of the analyte species (in moles per cubic centimeter). Note that Eq. 10.18 indicates a linear relationship for limiting current and concentration. The same equation applies for detecting reduced species by an oxidation reaction at the working electrode. In this case, by convention, the resulting anodic current is considered a negative current. As shown in Fig. 10.6, the potential of the working electrode that corresponds to a current that is exactly one-half the limiting current is termed $E_{1/2}$. This value is independent of analyte concentration. The $E_{1/2}$ is determined by the thermodynamics (E^0) of the given redox reaction, the solution conditions (e.g., if protons are involved in reaction, then pH will influence $E_{1/2}$), and any overpotential caused by slow electron transfer at a particular working electrode surface. The $E_{1/2}$ values are indicative of a given species undergoing an electrochemical reaction under specified conditions; hence the $E_{1/2}$ values enable distinguishing one electroactive species from another in the same sample. If the $E_{1/2}$ values for various species differ significantly (e.g., more than 120 mV), then measurements of several limiting currents in a given voltammogram yield quantitative results for several different species simultaneously.

Electrochemical cells used to carry out voltammetric or amperometric measurements can involve a two- or three-electrode configuration. In the two-electrode mode, external voltage is applied between the working electrode and a reference electrode, and the current is monitored. Because current passes through the reference electrode, such current can alter the surface concentration of electroactive species that poises the half-cell potential of the reference electrode, changing its value by a concentration polarization process. For example, if an Ag/AgCl reference electrode were used in a cell in which a reduction reaction for the analyte occurs at the working electrode, then an oxidation reaction would take place at the surface of the reference electrode:

Hence the activity and/or concentration of Cl^- ions near the surface of the electrode would decrease, which would make the potential of the reference electrode more positive than its true equilibrium value based on the actual activity of the Cl^- ion in the reference half-cell, because the Nernst equation for this half-cell is:

$$E_{\text{Ag/AgCl}} = E_{\text{AgCl/AgCl}}^0 - 0.059 \log \left(a_{\text{Cl}^-}^{\text{surface}} \right) \quad (10.20)$$

Such concentration polarization of the reference electrode is prevented by keeping the current density (amperes per square centimeter) low at the reference electrode. This is achieved in practice by making sure that the area of the working electrode in the electrochemical cell is much smaller than the surface area of the reference electrode; hence the total current flow will be limited by this much smaller area, and current density values at the reference will be very small to prevent concentration polarization.

A three-electrode potentiostat is often used to completely eliminate changes in reference electrode half-cell potentials. In simple terms, the potentiostat applies a voltage to the working electrode, which is measured versus a reference electrode via a zero-current potentiometric-type measurement, but the current flow is between the working electrode and a third electrode, called the counter electrode. Thus if reduction takes place at the working electrode, oxidation would occur at the counter electrode, but no net reaction would take place at the surface of the reference electrode because no current flows through this electrode. A potentiostat circuit is relatively simple to construct using modern operational amplifiers.

In voltammetric methods, E_{appl} is varied via some waveform to alter the working electrode potential as a function of time and the resulting current measured. The current change occurs at the decomposition potential range, which is best when specific for a given analyte. However, the location of the current response as a function of E_{appl} provides information on the nature of the species present (e.g., $E_{1/2}$), along with a concentration-dependent signal. This scan of E_{appl} can be linear (linear sweep voltammetry), or it can have more complex shapes to enhance sensitivity for monitoring concentration of a given electroactive species (e.g., normal pulsed voltammetry, differential pulse voltammetry, square wave voltammetry).

Amperometric methods differ from voltammetry in that E_{appl} is fixed, generally at a potential value in the limiting current plateau region of the voltammogram, and the resulting current is proportional to concentration. Amperometry can be more sensitive than common voltammetric methods because background charging currents, which arise from changing the E_{appl} as a function of time in voltammetry, do not exist. Hence, when selectivity can be ensured at a given E_{appl} value, amperometry may be preferred to voltammetric methods for more sensitive quantitative measurements.

Applications

Molecular O_2 is capable of undergoing several reduction reactions, all with a significant overpotential at solid electrodes, such as Pt, Au, or Ag. For example, the following reaction:

exhibits an $E_{1/2}$ at approximately -0.500 V on a Pt electrode (vs. a Ag/AgCl reference electrode), with a limiting current plateau beginning at approximately -0.600 V. This reaction is used to monitor the PO_2 in blood, which is the basis of the widely used amperometric O_2 sensor (Fig. 10.8). This device uses a small area planar Pt electrode as a working electrode (encased in insulating glass or other material) and an Ag/AgCl reference electrode, typically with a cylindrical design. This two-electrode electrolytic cell is placed within a sensor housing, on which a gas-permeable membrane (e.g., polypropylene, silicone rubber, Teflon) is held at the distal end. The inner working Pt electrode is pressed tightly against the gas-permeable membrane to create a thin film of internal electrolyte solution (usually buffer with KCl added). O_2 in the sample can permeate across the membrane and is reduced in accordance with the above electrochemical reaction. An E_{appl} of -0.650 or -0.700 V versus Ag/AgCl (within the limiting current regime) to the Pt working electrode will result in an observed current that is proportional to PO_2 present in the sample (including whole blood). In the absence of any O_2 , the current at this applied voltage under amperometric conditions will be near zero.

The outer gas-permeable membrane enables the electrode to detect O_2 with high selectivity over other easily reduced species that might be present in a given sample (e.g., metal ions, cystine). Only other gas species or highly lipophilic organic species can partition into and pass through such gas-permeable membranes. One type of interference in clinical samples can be caused by certain anesthesia gases, such as nitrous oxide, halothane, and isoflurane. These species can also diffuse through the outer membrane of the sensor, can be electrochemically reduced at the Pt electrode, and can yield a falsely high value for the measurement of PO_2 . However, optimized gas-permeable membrane materials and appropriate control of the applied potential to the cathode of the sensor have greatly reduced this problem in modern instruments. The outer gas-permeable membrane also helps restrict

Fig. 10.8 Design of an amperometric oxygen sensor used to monitor partial pressure of oxygen in blood. Ag/AgCl, Silver–silver chloride; H₂O, water; Pt, platinum.

diffusion of analyte to the inner working electrode; hence the membrane can control the mass transport of analyte (D/δ term in Eq. 10.18), such that in the presence or absence of sample convection, mass transport of O₂ to the surface of the Pt working electrode is essentially the same.

Amperometric PO₂ sensors can be used to detect other gas species by altering the applied voltage to the working electrode. For example, it is possible to detect nitric oxide (NO) with high selectivity using a similar gas electrode design in which the Pt is polarized at +0.900 versus Ag/AgCl to oxidize diffusing NO to nitrate at the Pt anode. Such NO sensors can be used for a variety of biomedically important studies to measure the amount of NO locally at or near the surface of various NO-producing cells.

Beyond amperometric devices, one specialized method of detecting trace concentrations of toxic metal ions in clinical samples is anodic stripping voltammetry (ASV). In ASV a carbon working electrode is used (sometimes further coated with an Hg film), and the E_{appl} is first fixed at a negative E_{appl} voltage so that all metal ions in the solution will be reduced to elemental metals (M^0) within the Hg film and/or on the surface of the carbon. Then the E_{appl} is scanned more positively, and reduced metals deposited in and/or on the surface of the working electrode are reoxidized, giving a large anodic current peak proportional to the concentration of metal ions in the original sample. The potential at which these peaks are observed indicates which metal is present, and the height of the stripping peak current is directly proportional to the concentration of the metal ion in the original sample. Such ASV techniques can be used to detect the total concentration of lead in whole blood samples, providing a rapid screening method for lead exposure and poisoning.

Although voltammetric and/or amperometric techniques can be applied to detect a wide range of species, the selectivity offered for measurements in complex clinical samples—where many species can be electroactive—is rather limited. For example, as stated in the previous discussion relevant to the O₂ sensor, in the absence of the gas-permeable membrane, other species that can be reduced at or near the same E_{appl} as O₂ would cause significant interference.

To expand the range of analytes that can be detected with voltammetric and/or amperometric methods, electrochemical techniques can be used as highly sensitive detectors for high-performance liquid chromatography systems (see Chapter 12). In liquid chromatography with electrochemical detection (LC-EC), eluting solutes are detected by flow-through electrodes (usually carbon or Hg) designed to have extremely low dead volumes (Fig. 10.9). The electrodes can be operated in amperometric or voltammetric modes (with high scan speeds), and several electrodes can be operated simultaneously in series or in parallel flow arrangements to gain additional selectivity. For example, homocysteine can be measured with (1) the addition of reducing agents to a serum sample to generate free homocysteine, (2) precipitation of proteins in the sample (with trichloroacetic acid), and (3) separation of the serum components on a reversed-phase octadecylsilane high-performance liquid chromatography column. The eluting homocysteine is detected and measured with online electrochemical detection via homocysteine oxidation to the corresponding mercuric dithiolate complex:

Fig. 10.9 Schematic of liquid chromatography with electrochemical detection system, with electrochemical detector monitoring elution of analytes from a high-performance liquid chromatography (HPLC) column by their oxidation or reduction at a suitable thin-layer working electrode. EC, Electrochemical.

using a thin-layer Hg/Au amalgam electrode poised at +0.150 V versus Ag/AgCl. Integration of the eluting band for homocysteine provides quantitative results, with high selectivity. Similarly, catechols and catecholamines can be readily detected in serum by a similar LC-EC method, with eluted catechols oxidized to quinones at a flow-through carbon working electrode poised at potentials typically more than +0.200 V versus Ag/AgCl. Furthermore, a host of therapeutic drugs can also be quantified in serum or urine via LC-EC methods.

POINTS TO REMEMBER

Predominant Types of Electrochemical Sensor Technologies Used in Whole Blood Analyzers

- Potentiometry: for measurement of pH, PCO_2 , and electrolytes
- Amperometry: for measurement of PO_2 and as the basis for whole blood glucose and lactate biosensors
- Conductometry: for measurement of hematocrit

CONDUCTOMETRY

Conductometry is an electrochemical technique used to determine the quantity of an analyte present in a mixture by measuring its effect on the electrical conductivity of the mixture. It is the measure of the ability of ions in solution to carry current under the influence of a potential difference. In a conductometric cell, potential is applied between two inert metal electrodes. An alternating potential with a frequency between 100 and 3000 Hz is used to prevent polarization of the electrodes. A decrease in solution resistance results in an increase in conductance, and more current is passed between the electrodes. The resulting current flow is also alternating. The current is directly proportional to solution conductance. Conductance is considered the inverse of resistance and may be expressed in units of ohm^{-1} (siemens). In clinical analysis,

conductometry is frequently used for measurement of the volume fraction of erythrocytes in whole blood (hematocrit) and as the transduction mechanism for some biosensors.

Erythrocytes act as electrical insulators because of their lipid-based membrane composition. This phenomenon was used first in the 1940s to measure the volume fraction of erythrocytes in whole blood (hematocrit) by conductivity and is used currently to measure hematocrit on multianalyte instruments for clinical analysis. The conductivity of whole blood depends not only on the volume fraction and shape of the erythrocytes but also on the conductivity of the surrounding plasma. An increase in the volume fraction of erythrocytes that are less conductive than the surrounding plasma leads to a decrease in conductivity shown by the following relationship:

$$G_b = \frac{a}{1 + \frac{H}{100 - H} \times c} \quad (10.23)$$

where G_b = conductivity of whole blood; a = plasma conductivity; H = hematocrit in percent; and c = factor for erythrocyte orientation. In practice, plasma conductivity also contains correction factors for Na^+ and K^+ concentrations. These cations are usually measured in conjunction with hematocrit on systems designed for clinical analysis.

Conductivity-based hematocrit measurements have limitations. Abnormal protein concentrations will change plasma conductivity and interfere with the measurement. Low protein concentrations resulting from dilution of blood with protein-free electrolyte solutions during cardiopulmonary bypass surgery will result in erroneously low hematocrit values by conductivity. Preanalytical variables, such as insufficient mixing of the sample, will also lead to errors. Hemoglobin is the preferred analyte to monitor blood loss and the need for transfusion during trauma and surgery. However, electrochemical measurement of hematocrit in conjunction with blood gases and electrolytes remains in use mainly because of its simplicity and convenience, despite some limitations.

Another clinical application of conductance is for electronic counting of blood cells in suspension. Termed the Coulter principle, it relies on the fact that the conductivity of blood cells is lower than that of a salt solution used as a suspension medium. The cell suspension is forced to flow through a tiny orifice. Two electrodes are placed on either side of the orifice, and a constant current is established between the electrodes. Each time a cell passes through the orifice, resistance increases; this causes a spike in the electrical potential difference between the electrodes. The pulses are then amplified and counted.

COULOMETRY

Coulometry measures the electrical charge passing between two electrodes in an electrochemical cell. The amount of charge passing between the electrodes is directly proportional to oxidation or reduction of an electroactive substance at one of the electrodes. The number of coulombs transferred in this process is related to the absolute amount of electroactive substance by the Faraday law:

$$Q = n \times N \times F \quad (10.24)$$

where Q = amount of charge passing through the cell (unit: C = coulomb = ampere $\times$ second); n = the number of electrons transferred in the oxidation or reduction reaction; N = the amount of substance reduced or oxidized in moles; and F = Faraday constant (96,487 coulombs/mol).

Current is the amount of charge passed per unit time (ampere = coulomb per second). Coulometry is used in clinical applications for the determination of Cl^- in serum or plasma and as the mode of transduction in certain types of biosensors.

Commercial coulometric titrators have been developed for determination of Cl^- . A constant current is applied between a silver wire (anode) and a platinum wire (cathode). At the anode, Ag is oxidized to Ag^+ . At the cathode, H^+ is reduced to H_2 gas. At a constant applied current, the number of coulombs passed between the anode and the cathode is directly proportional to time (coulombs = amperes $\times$ seconds). Therefore the absolute number of Ag^+ ions produced at the anode may be calculated from the amount of time current passes through it. In the presence of Cl^- , Ag^+ ions are precipitated as $\text{AgCl}_{(s)}$, and the amount of free Ag^+ in solution is low. When all Cl^- ions have been complexed, a sudden increase in the concentration of Ag^+ in solution is noted. Excess Ag^+ is sensed amperometrically at a second Ag electrode, which is polarized at negative potential. The excess Ag^+ is reduced to Ag, producing a current. When this current exceeds a certain value, the titration is stopped. The absolute number of Cl^- ions present in the sample is calculated from the time during which titration with Ag^+ was in progress. Because the volumetric amount of serum or plasma sample is known, it is possible to calculate the concentration of Cl^- in the sample. Coulometric titration is one of the most accurate electrochemical techniques because the method measures the absolute quantity of electroactive substance in the sample.

Fig. 10.10 General design for an in vitro optical sensor to detect a given analyte (A) in blood. Polymer film contains dye that changes spectral properties in proportion to the amount of analyte in the sample phase. Example shown is for a sensing film that changes luminescence (fluorescence or phosphorescence).

Coulometry is considered the “gold standard” for determination of Cl^- in serum or plasma. However, the method is subject to interference from anions in the sample that have greater affinity for Ag^+ than Cl^- (e.g., bromide) and is not commonly used currently in clinical laboratories.

OPTICAL CHEMICAL SENSORS

An **optode** is an optical sensor used in analytical instruments to measure blood gases and electrolytes. Optodes have certain advantages over electrodes, including (1) ease of miniaturization, (2) less noise (no transduction wires), (3) potential long-term stability using ratiometric-type measurements at multiple wavelengths, and (4) they do not require a separate reference electrode. These advantages initially promoted the development of optical sensor technology for the design of intravascular blood gas sensors. However, the same basic sensing principles can be used in clinical chemistry instrumentation designed for more classic in vitro measurements on discrete samples. In such systems, light can be brought to and from the sensing site by optical fibers or simply by appropriate positioning of light sources (light-emitting diodes), filters, and photodetectors to monitor absorbance (by reflectance), fluorescence, or phosphorescence (Fig. 10.10).

Basic Concepts

Optical sensors devised for PO_2 measurements are typically based on immobilization of certain organic dyes (e.g., pyrene, diphenylphenanthrene, phenanthrene, fluoranthene) or metal ligand complexes (e.g., ruthenium[II] tris[dipyridine], Pt and palladium metalloporphyrins) within hydrophobic polymer films (e.g., silicone rubber) in which O_2 is soluble. The fluorescence or phosphorescence of such species at a given

wavelength is often quenched in the presence of paramagnetic species, including molecular O_2 . In the case of embedded fluorescent dyes, the intensity of the emitted fluorescence of such films will decrease in proportion to the PO_2 in the sample in contact with the polymer film, in accordance with:

$$\frac{I_0}{I_{PO_2}} = 1 + kPO_2 \quad (10.25)$$

where I_0 = fluorescence intensity in the absence of any O_2 ; I_{PO_2} = fluorescence intensity at a given PO_2 ; and k = a quenching constant for the particular fluorophore used.

Hence a linear relationship exists between the ratio I_0/I_{PO_2} and the PO_2 in the sample phase. The larger the quenching constant, the greater is the degree of quenching for the given fluorophore. However, it is important that the quenching constant is in a range that will yield linear behavior over the physiologically relevant range of PO_2 in blood. For example, if k is too large, then the maximum quenching possible will occur over a range of PO_2 that is less than physiologic.

Phosphorescence intensity or phosphorescence lifetime measurements of immobilized metal ligand complexes can also be used (i.e., binding of O_2 decreases excited state lifetimes). Sensors based on changes in luminescent lifetime have the inherent advantage of being insensitive to perturbations in the optical path length and the amount of active dye present in the sensing layer.

Optical pH sensors require immobilization of appropriate pH indicators (e.g., fluorescein, 8-hydroxy-1,2,6-pyrene trisulfonate, phenol red) within thin layers of hydrophilic polymers (e.g., hydrogels) because equilibrium access of protons to the indicator is essential. The absorbance or fluorescence of the protonated or deprotonated form of the species can be used for sensing purposes. One issue with respect to using immobilized indicators for accurate physiologic pH measurements is the effect of ionic strength on the acid dissociation constant (pK_a) of the indicator. Because optical sensors measure the concentration of protonated or deprotonated dye as an indirect measure of H^+ ion activity, variations in ionic strength of the physiologic sample can influence the accuracy of the pH measurement.

Applications

Optical sensors suitable for the determination of PCO_2 use optical pH transducers (with immobilized indicators) as inner transducers in an arrangement similar to a classical electrochemical sensor design (see Fig. 10.4). The addition of bicarbonate salt within the pH-sensing hydrogel layer creates the required electrolyte film layer, which varies in pH depending on the PCO_2 in equilibrium with the film. The optical pH sensor is covered by an outer gas-permeable hydrophobic film (e.g., silicone rubber) to prevent proton access, yet it allows CO_2 equilibration with the pH sensing layer. As the PCO_2 in the sample increases, the pH of the bicarbonate layer decreases, and the corresponding decrease in the deprotonated form of the indicator (or increase in the protonated form) is sensed optically.

Two approaches have been used to sense electrolytes optically in physiologic samples. One method uses many of the same lipophilic ionophores developed for polymer membrane-type ISEs (see Fig. 10.3). These species are doped into thin hydrophobic polymeric films, along with a lipophilic pH indicator. In the case of cation ionophores (e.g., valinomycin for sensing K^+), when cations from the sample are extracted by the ionophore into the thin film, the pH indicator (RH) loses a proton to the sample phase to maintain charge neutrality within the organic film (yielding R^-). This results in a change in the optical absorption or fluorescence spectrum of the polymer layer. If the thickness of the films is kept at less than 10 μm , equilibrium response times on the order of less than 1 minute have been achieved. The main limitation of this design is that the pH of the sample phase also influences the overall extraction equilibrium for ions into the film. Thus simultaneous and independent measurement of sample pH is required or buffered dilution and/or pH control of the sample phase is necessary to obtain accurate measurements of electrolytes.

A second technique used to sense electrolyte ions is immobilization of a cation and/or anion recognition agent within a hydrogel matrix, similar to the pH sensors described earlier. The recognition agent in this case is not usually lipophilic; therefore it must be covalently anchored to the hydrogel, so that it does not leach into the sample phase. The agent is designed so that selective cation or anion binding alters the absorbance or fluorescence spectrum of the species within the hydrogel. Typically this is achieved by linking ion recognition and chromophoric properties within a single organic molecule. Such ion sensors have been used successfully in at least one commercial blood gas–electrolyte analyzer using an array of sensors of the generic design similar to that in Fig. 10.10.

BIOSENSORS

A **biosensor** is a specific type of chemical sensor consisting of a biologic recognition element and a physicochemical transducer, often an electrochemical or an optical device. The biologic element is capable of recognizing the presence and activity and/or concentration of a specific analyte in solution. The recognition may be a *biocatalytic reaction* (enzyme-based biosensor) or a *binding process* (affinity-based biosensor) when the recognition element is, for example, an antibody, DNA segment, or cell receptor. Interaction of the recognition element with a target analyte results in a measurable change in a solution property locally at the surface of the device, such as formation of a product or consumption of a reactant. The transducer converts the change in solution property into a quantifiable electrical signal. The mode of transduction may be one of several, including electrochemical or optical measurement and measurement of mass or heat. The present discussion is limited to biosensors based on electrochemical and optical modes of transduction because they constitute most biosensors used for clinical applications.

POINTS TO REMEMBER

Biosensors

- Biosensors measure substances lacking direct electroactive or optical properties.
- Biosensors consist of a biologic recognition element and a physicochemical (e.g., electrochemical or optical) transducer.
- Interaction of a biologic recognition element and an analyte results in either a biocatalytic reaction or a binding process, producing a measurable signal.
- Biosensors are used in most commercial blood glucose meters.
- Sensors for whole blood measurements without a biologic recognition element (e.g., ISEs) are not considered biosensors.

Enzyme-Based Biosensors With Amperometric Detection

Enzyme-based biosensors based on electrochemical transducers, specifically amperometric electrodes, are most commonly used for clinical analyses and are frequently cited in the literature. Most of the current blood glucose meters are based on measurements using enzyme-based biosensors with amperometric detection, with glucose sensors produced in single-use formats. The first amperometric biosensor was used to measure glucose in blood and was based on immobilized glucose oxidase on the surface of an amperometric PO_2 sensor. A solution of glucose oxidase was physically entrapped between the gas-permeable membrane of the PO_2 electrode and an outer semipermeable membrane (Fig. 10.11). The outer membrane was of a low-molecular-weight cutoff to allow the substrate (glucose) and O_2 from the sample to pass, but not proteins and other macromolecules. In this way, enzymes could be concentrated at the sensor's surface. Oxidation of glucose, catalyzed by glucose oxidase as follows:

consumes O_2 near the surface of the sensor. The rate of decrease in PO_2 is a function of the glucose concentration and is monitored by the PO_2 electrode. A steady-state PO_2 can be achieved at the surface in a short period of time, yielding a steady-state current value that decreases as a function of glucose concentration in the sample.

If the polarizing voltage of the PO_2 electrode is reversed, making the Pt electrode positive (anode) relative to the Ag/AgCl reference electrode, and if the gas-permeable membrane is replaced with a hydrophilic outer membrane containing the immobilized enzyme, it is possible to oxidize the hydrogen peroxide (H_2O_2) produced by the glucose oxidase as follows:

The steady-state current produced is now directly proportional to the concentration of glucose in the sample.

In practice, a sufficiently high voltage (overpotential) must be applied to the platinum anode to drive the oxidation of the H_2O_2 . An applied voltage of +0.7 V or greater (relative to Ag/AgCl) is typically used. Fig. 10.12 illustrates this basic H_2O_2 detection design, which is suitable for use in devising clinically useful sensors for glucose but also for a host of other substrates for which suitable oxidase enzymes generate H_2O_2 .

Immobilization of enzymes in the early biosensors was a simple entrapment method behind a membrane of low-molecular-weight cutoff; this approach is still used in some commercial applications. Many other schemes for enzyme immobilization for biosensor development have been suggested. The most common are cross-linking of the enzyme with an inert protein (e.g., bovine serum albumin) using glutaraldehyde, simple adsorption of enzyme to electrode surfaces, and covalent binding of enzymes to insoluble carriers (e.g., nylon or glass). Another immobilization technique involves bulk modification of an electrode material, mixing

Fig. 10.11 Illustration of an enzyme-based biosensor prepared using oxidase enzyme immobilized at the surface of an amperometric partial pressure of oxygen sensor. Increase in substrate concentration (S) reduces the amount of oxygen present at the surface of the sensor. H_2O_2 , Hydrogen peroxide.

enzymes with carbon paste, which serves as both the enzyme immobilization matrix and the electroactive surface.

One of the first biosensor-based systems for the measurement of glucose in blood used amperometric detection of H_2O_2 as the measurement principle. Dependence of the measured glucose value on O_2 concentration in the sample was a problem because significantly less than the stoichiometric amount of dissolved O_2 is present in blood to support the glucose oxidase reaction and to produce a linear relationship of signal with glucose concentration. This is especially true at high concentrations of glucose found in samples from patients with diabetes (greater than 500 mg/dL; 27.8 mmol/L). So, sample and calibration solutions were diluted at least 1:10 in buffer for equilibrium with atmospheric PO_2 to fix the O_2 concentration in the calibrator and sample to a constant value.

The problem of O_2 limitation for biosensors based on oxidase enzymes has been addressed by designing semipermeable membranes that restrict diffusion of the primary analyte (substrate) to the enzyme layer, which avoids saturation of the enzyme and keeps the ratio of O_2 to analyte always in excess of 1. This extends the linearity of response

Fig. 10.12 (A) Design of an amperometric enzyme-based biosensor based on anodic detection of hydrogen peroxide (H_2O_2) generated from an oxidase enzymatic reaction (e.g., glucose oxidase). (B) Expanded view of the sensing surface shows the different membranes and electrochemical processes that yield the anodic current proportional to the substrate concentration in the sample. Ag/AgCl, Silver–silver chloride; K , proportionality constant; MW, molecular weight; Pt, platinum; rbc, red blood cells. (From Meyerhoff, M. [1990]. New in vitro analytical approaches for clinical chemistry measurements in critical care. *Clinical Chemistry*, 36, 1570.)

to analyte concentrations substantially higher than the K_m of the enzyme and reduces the signal dependence on O_2 . Outer track-etched polycarbonate membranes are commonly used, as are membranes of PVC, polyurethanes, and silicone emulsions. Another approach has been to use an O_2 -rich electrode material as a reservoir of O_2 to support the bioreaction. A fluorocarbon (Kel-F Oil) has been used to formulate a carbon paste electrode to act as a source of O_2 and as the working electrode.

Electron acceptors other than O_2 can serve as mediators in the glucose oxidase reaction and completely eliminate any dependence of the amperometric response on the O_2 concentration of the sample. The mediator, which is usually coimmobilized with the enzyme, transports electrons to the anode surface, where it is reoxidized, resulting in a cyclic reaction mechanism (Fig. 10.13). Mediators with electron transfer kinetics (little or no overpotential) more favorable than that of O_2 allow operation of the sensor at lower applied potentials (+0.2 V vs. Ag/AgCl or lower) than those that are typically used for the oxidation of H_2O_2 . This approach not only eliminates dependency of the reaction rate on O_2 , the lower applied potential serves to reduce the contribution from oxidizable interfering substances (e.g., uric acid, ascorbic acid, acetaminophen) to the sensor response. Examples of mediators that have been used include quinones and conductive organic salts, such as tetrathiafulvalene-tetracyanoquinodimethane. Ferricyanide and ferrocene derivatives have also been used, including early commercial applications for home blood glucose monitoring. Dimethylferrocene is impregnated into a graphite electrode to which glucose oxidase has been immobilized. Reduced glucose oxidase from the enzymatic reaction is reoxidized by the electrochemically generated ferricinium ion. Current produced during this cycling mechanism is proportional to the concentration of glucose in the blood sample.

Another technique used to decrease interferences from easily oxidized species in a blood sample when traditional H_2O_2 electrochemical detection is used is to employ selectively permeable membranes in proximity to the electrode surface that allow transport of H_2O_2 to the electrode surface but reject the interfering substances based on size exclusion (see Fig. 10.12B). An example is as simple as a

Fig. 10.13 The use of an electroactive mediator in the design of an amperometric enzyme-based biosensor. The mediator accepts electrons directly from the enzyme and is oxidized at the surface of the working electrode, creating more oxidized mediator to continue this process. Ox, Oxidant; Red, reductant. (From D'Orazio, P. [2002]. In K. Lewendrowski [Ed.]. *Clinical chemistry: laboratory management and clinical correlations* [p. 464]. Philadelphia: Lippincott, Williams & Wilkins.)

low-molecular-weight cutoff membrane, such as cellulose acetate, which is used in many commercial amperometric biosensors. Electropolymerized films, such as poly(phenylenediamine) formed in situ, are also used, to reject interfering substances based on size. Another approach used in a commercial application involves using a second correcting electrode, identical to the working electrode but without enzyme that is sensitive only to the presence of oxidizable interfering substances. The resulting differential signal is proportional to the concentration of analyte.

A novel approach used for elimination of electroactive interfering substances in a commercially available glucose sensor is to directly “wire” the redox center of the enzyme glucose oxidase to a metallic, amperometric electrode using an osmium (III/IV)-based redox hydrogel. Osmium sites effectively serve as mediators and can accept electrons directly from the entrapped enzyme, without need for O_2 . This approach allows the operating potential of the electrode to be dramatically lowered to +0.2 V versus the saturated calomel reference electrode, where currents resulting from electro-oxidation of ascorbate, urate, acetaminophen, and L-cysteine are negligible.

Substitution of other oxoreductase enzymes for glucose oxidase allows amperometric biosensors for other substrates of clinical interest to be constructed. For example, sensors have been developed to measure (1) blood lactate, (2) cholesterol, (3) pyruvate, (4) alanine, (5) glutamate, and (6) glutamine. In addition, by using a multiple enzyme cascade including an oxoreductase enzyme, an amperometric biosensor for creatinine has been developed.

Enzyme-Based Biosensors With Potentiometric and Conductometric Detection

ISEs can be used as transducers in potentiometric biosensors. An example is a biosensor for urea (blood urea nitrogen [BUN]) based on a polymer membrane ISE for NH_4^+ ion (Fig. 10.14). The enzyme urease is immobilized at the surface of the NH_4^+ -selective ISE based on the antibiotic nonactin (see structure of ionophore in Fig. 10.3) and catalyzes the hydrolysis of urea to NH_3 and CO_2 :

The ammonia (NH_3) produced forms NH_4^+ , which is sensed by the ISE. The signal generated by the NH_4^+ produced is proportional to the logarithm of the concentration of urea in the sample. The response may be steady state or transient. Typically, correction for background K^+ is required because the nonactin ionophore has limited selectivity for NH_4^+ over K^+ ($K_{NH_4/K} = 0.1$). Potassium is measured simultaneously with urea and is used to correct the output of the urea sensor using Eq. 10.9.

The approach already described for measurement of urea using an enzyme-based potentiometric biosensor assumes that the turnover of urea to NH_4^+ at steady state provides a constant ratio of NH_4^+ to urea, independent of concentration. This is rarely the case, especially at higher substrate concentrations, which results in a nonlinear sensor response.

Fig. 10.14 Potentiometric enzyme-based biosensor for determination of blood urea, based on urease enzyme immobilized on the surface of an ammonium ion-selective polymeric membrane electrode. CO_2 , Carbon dioxide; K^+ , potassium; NH_4^+ , ammonium; *rbc*, red blood cells.

The linearity of the sensor is also limited by the fact that hydrolysis of urea produces a local alkaline pH in the vicinity of the NH_4^+ -sensing membrane, partially converting NH_4^+ to NH_3 ($pK_a = 9.3$). Ammonia is not sensed by the ISE. The degree of nonlinearity may be reduced by the placement of a semi-permeable membrane between the enzyme and the sample to restrict diffusion of urea to the immobilized enzyme layer.

A change in solution conductivity has also been used as a transduction mechanism in enzyme-based biosensors. Examples include the measurement of glucose, creatinine, and acetaminophen using interdigitated electrodes. There are few practical applications of conductometric biosensors because of the variable ionic background of clinical samples and the requirement to measure small conductivity changes in media of high ionic strength. A commercial system for the measurement of urea in serum, plasma, and urine is based on the enzyme urease. Dissolution of products from Eq. 10.28 to NH_4^+ and HCO_3^- produces a change in sample conductivity. The initial rate of change in conductivity is measured to compensate for the background conductivity of the sample. This approach is limited to the measurement of analytes at relatively high concentrations because of small changes in conductivity produced by low concentrations of analyte.

Enzyme-Based Biosensors With Optical Detection

Optical sensors with immobilized enzymes and indicator dyes have been developed for the measurement of glucose

and other substrates of clinical interest. These biosensors are based on optical detection chemistries for pH and O_2 , described earlier in this chapter, and rely on absorbance and/or reflectance, fluorescence, and luminescence as modes of detection. Enzyme immobilization methods resemble those used to construct electrochemical biosensors, including physical entrapment or encapsulation in a gel matrix, physical adsorption onto substrates, and covalent binding or absorption on an insoluble support. Using an example based on an optode for PO_2 , a sensitive indicator is coimmobilized with an oxidase enzyme at the end of a fiberoptic probe. The probe is used to monitor fluorescence of the indicator. Quenching of fluorescence of the indicator by O_2 is followed. A decrease in PO_2 resulting from a reaction catalyzed by the enzyme will result in less quenching of the indicator and a fluorescent signal directly proportional to the concentration of the substrate. In an example of an optical biosensor probe for glucose, an O_2 -sensitive cationic dye, $Ru(phen)_3^{2+}$, is immobilized, along with glucose oxidase, on the surface of an optical fiber. A decrease in PO_2 arising from the enzyme-catalyzed oxidation of glucose results in an increase in luminescence intensity of the ruthenium tris(phenanthrene).

Similar optical biosensors have been prepared for many other analytes. For example, a cholesterol optical biosensor has been devised based on fluorescence quenching of an O_2 -sensitive dye that is coupled to the consumption of O_2 resulting from the enzyme-catalyzed oxidation of cholesterol by the enzyme cholesterol oxidase. Serum bilirubin has been detected using bilirubin oxidase, coimmobilized with a ruthenium dye, on an optical fiber. The bilirubin sensor was reported to exhibit a lower detection limit of 0.6 mg/dL (10 μ mol/L), a linear range up to 1.8 mg/dL (30 mmol/L), and a typical reproducibility of 3% (coefficient of variation), adequate for clinical application.

The pH change resulting from enzyme-catalyzed reactions has also been measured optically. The indicator dye fluorescein is often used as a pH-sensitive indicator to construct such sensors. The protonated form of fluorescein does not fluoresce, but the conjugate base strongly fluoresces at 530 nm, when excited at 490 nm. Using glucose oxidase as the enzyme, a pH optode has been used to follow the formation of gluconic acid. A disadvantage of optical sensors based on pH changes is that they are strongly dependent on the pH and buffer capacity of the sample. Moreover, the working range of the sensor is determined by the pK_a of the indicator, 6.8 to 7.2 for fluorescein, depending on ionic strength of the sample matrix. A pH-sensitive indicator may also be used to follow enzymatic reactions that produce ammonia (e.g., urease action on urea).

Affinity Sensors

Affinity sensors are a special class of biosensors in which the immobilized biologic recognition element is a binding protein, antibody, or oligonucleotide with high binding affinity and high specificity toward a clinically important analyte. Such sensors are being developed as alternatives to conventional binding assays to enhance the speed and convenience

of a wide range of assays that normally would be run on large, sophisticated instruments in a central laboratory. Affinity sensors may be more easily adapted than traditional assays to systems developed for point-of-care testing for infectious disease, cardiac markers, or other cases where speed and ease of use are required. Ideally, direct binding of the immobilized species with its target in a clinical sample should yield a sensor signal proportional to the concentration of the analyte. However, in practice, direct sensing of the binding event at analyte concentrations that would cover the full range for clinical application is difficult to achieve. Furthermore, high affinity of such binding reactions, which is required to achieve optimal sensitivity, limits the reversibility of such devices. Unlike ISEs, O_2 sensors and many of the enzyme-based biosensors described previously, affinity sensors based on electrochemical, optical, or other transduction modes are typically single-use devices. For repeated multiuse applications, some type of regeneration step (pH change, temperature change, and so on) to dissociate the tight binding between the recognition element and the target is required.

Most affinity-type sensors appearing in the literature with promise of clinical usefulness are based on reagents labeled with enzymes, fluorophores, and electrochemical tags, and hence they function more like traditional binding and/or immunoassays, except that a recognition element is immobilized on the surface of a suitable electrode or another type of transducer. For example, electrochemical O_2 sensors have been used to carry out heterogeneous enzyme immunoassays (sandwich or competitive type), using catalase as a labeling enzyme (catalyzes $H_2O_2 \rightarrow 2H^+$ and O_2) and immobilizing capture antibodies on the outer surface of the gas-permeable membrane. After binding equilibration and washing steps, the amount of bound enzyme is detected by adding substrate and following the increase in current generation caused by local production of O_2 near the surface of the sensor.

The number of research reports related to affinity biosensors continues to increase, with potential application for detection of markers of cardiac disease, cancer, and autoimmune disease. Commercialization has lagged behind basic research, and movement of affinity biosensors from the research laboratory to the clinical laboratory has been slow. Some commercial examples of immunosensors do exist, primarily in the unit-use, disposable format designed for point-of-care testing. One successful commercial example is a cartridge-based device for cardiac troponin I on the i-STAT handheld analyzer (Abbott Point of Care, Abbott Laboratories). This sensor uses a sandwich immunoassay format with electrochemical detection. A capture antibody is immobilized on a gold electrode for recognition and capture of troponin in the blood sample. A second reporter antibody is labeled with alkaline phosphatase and binds with surface-captured troponin antigen. Following incubation and washing steps, the substrate p-aminophenyl phosphate is introduced, and the product of the enzymatic reaction (p-aminophenol) is detected amperometrically by oxidation at the gold electrode. Magnitude of the oxidative current is proportional to concentration of troponin in the sample.

Fig. 10.15 Examples of DNA biosensor configurations. (A) Direct electrooxidation (Ox) detection of guanine bases in target DNA after hybridization with immobilized capture probe on electrode surface. (B) Electrochemical detection of hybridization using exogenous redox (Ox) species that intercalate into hybridized complex between the immobilized capture DNA probe and target DNA.

Affinity Sensors for DNA Analysis Using Fluorescent Labels

Affinity-type sensors based on oligonucleotide binding represent perhaps the most promising application of affinity sensors to clinical chemistry. Fluorescent labels were the first to be used in an early commercial biosensor for DNA analysis, introduced in 1996 (GeneChip, Affymetrix, Santa Clara, CA). High-density oligonucleotide arrays are formed on glass substrates. Target DNA is isolated and amplified using the polymerase chain reaction (PCR) while a fluorescent label is incorporated. The sample is incubated on the array, and detection of hybridization of labeled DNA to its complementary strands takes place by monitoring light emitted by the fluorescent labels. The primary application of the device has been for DNA sequencing, so the focus has been primarily on increasing the density of the DNA arrays. Applications of the device continue to expand, with a variety of arrays developed for gene expression and whole genomic analysis related to (1) cancer, (2) inflammatory disease, (3) infectious disease, and (4) diabetes. Another commercial example of affinity sensors for DNA analysis using fluorescent labels is the BeadArray technology (Illumina, San Diego, CA). Silica microbeads with covalently attached, single-stranded DNA probes are randomly assembled on a fiberoptic bundle or planar silica surface. Each bead carries hundreds of thousands of copies of a gene-specific probe sequence. Due to the high-density packing of beads, with a possibility of approximately 50,000 beads on a 1.4-mm diameter array, a large number of probe sequences may be investigated in parallel, and multiple copies of each probe sequence are possible, increasing measurement precision. Fluorescently labeled target sequences in the

sample to be analyzed hybridize with their complementary probe sequences. Arrays are scanned in a BeadArray reader for image analysis and data extraction. This versatile platform has been adapted for various genetic analyses, such as single nucleotide polymorphism genotyping, DNA methylation detection, and gene expression profiling.

Affinity Sensors for DNA Analysis Using Electrochemical Labels

DNA sensors with immobilized complementary DNA on a suitable electrochemical sensor can operate in direct (electrochemical oxidation of guanine in target DNA; Fig. 10.15A) or indirect (exogenous electrochemical markers and/or labels; Fig. 10.15B) transduction modes. Although most of the proposed electrochemical DNA biosensors require amplification methods, such as PCR, to multiply small amounts of DNA into measurable quantities, some are sensitive enough to eliminate the need for target amplification. Nanotechnology has been proposed, in an indirect format, for signal amplification. For example, a capture probe DNA is immobilized on an Au electrode. Reporter probes with electrostatically bound ruthenium complexes ($\text{Ru}[\text{NH}_3]_6^{3+}$) are loaded onto Au nanoparticles (AuNP) and are capable of hybridizing with one of two sequences on target DNA. The other sequence on the target DNA is capable of hybridizing with the immobilized capture probe. Hybridization events on the electrode surface bring multiple reporter probes for each AuNP. Electroactive ($\text{Ru}[\text{NH}_3]_6^{3+}$) is reduced at the electrode surface, and the coulometric signal is proportional to the concentration of target DNA. A commercial example of electrochemical DNA sensing, along with AuNP probes without

need for PCR amplification, is the Verigene system (Luminex, Austin, TX), which is capable of detecting single-nucleotide polymorphisms related to common genetic disorders, such as (1) thrombophilia, (2) alterations of folate metabolism, (3) cystic fibrosis, and (4) hemochromatosis. Another commercially available, electrochemically based platform uses a sensor array chip consisting of 16 nanoscale Au electrodes, modified with thiol self-assembled monolayers, optimized for biomolecule immobilization. Horseradish peroxidase is the preferred target label because of its fast electron transfer kinetics, when used with amperometric detection.

Another example of an electrochemical “gene” sensor array uses electrochemical probes that are selectively inserted into hybridized DNA duplexes. In one approach, after the immobilized capture of oligo anchored to the electrode surface is allowed to bind the target sequence, hybridization is detected by exposing the surface of the electrode to an exogenous electroactive species (e.g., Co[III]tris-phenanthroline or ruthenium complexes) that intercalates within the duplex but not to single-stranded DNA. After unbound electroactive

species are removed by washing, the presence of hybridization is readily detected by voltammetry, scanning the potential of the underlying electrode to oxidize or reduce any intercalated electroactive species, with the current detected being proportional to the number of duplex DNA species on the surface of the electrode.

POINTS TO REMEMBER

Affinity Biosensors

- Affinity biosensors are a specific type of biosensor in which an immobilized recognition element exhibits a high binding constant for the analyte of interest.
- Examples of recognition elements are antibodies and oligonucleotides (DNA segments).
- Affinity biosensor binding reactions are typically irreversible and best suited to single-use sensors.
- Most affinity biosensors for clinical application use indirect modes of transduction, based on reagent label such as enzymes, fluorescent, and electrochemical labels.

REVIEW QUESTIONS

1. Ion-selective electrodes measure electrical potential difference across a membrane using the principles of:
 - a. coulometry.
 - b. potentiometry.
 - c. amperometry.
 - d. conductivity.
2. An optical sensor used in analytical instruments to measure pH, blood gases, and electrolytes is referred to as a(n):
 - a. potentiometer.
 - b. optode.
 - c. affinity-type sensor.
 - d. coulometer.
3. Voltammetry/amperometry measurements are based on which of the following electrochemical cell types?
 - a. Ion-selective electrode cells
 - b. Galvanic electrochemical cells
 - c. Electromotive force cells
 - d. Electrolytic electrochemical cells
4. An affinity-based biosensor is one in which:
 - a. the biologic element recognizes the analyte on the basis of its binding to an immobilized substance.
 - b. the fluorescence of a solution is coupled to an enzyme-catalyzed reaction.
 - c. the biologic element reacts with an ion-selective electrode that is used as a potentiometric transducer.
 - d. an electron acceptor is used to form a colored reaction product.
5. A voltmeter that measures the potential across an electrochemical cell (between the two electrodes) is referred to as a:
 - a. conductometer.
 - b. amperometer.
 - c. direct-reading potentiometer.
 - d. redox meter.
6. Membrane potentials caused by the permeability of certain types of membranes to selected anions or cations are measured by which type of electrode?
 - a. Ion-selective electrode
 - b. Saturated calomel electrode
 - c. Platinum electrode
 - d. Gas-sensing electrode
7. The maximum difference in potential between the two electrodes in an electrochemical cell obtained with the current at zero is the definition of:
 - a. electrical potential.
 - b. electromotive force.
 - c. electrochemical gradient.
 - d. Nernst equation.
8. In this type of measurement, a constant current is applied to a solution, and a substance in that solution is changed to a different state through oxidation or reduction. The time it takes for this to occur is measured. This electrochemical technique is called:
 - a. amperometry.
 - b. voltammetry.
 - c. potentiometry.
 - d. coulometry.

9. The measurement of ions by direct potentiometry provides a value for the concentration of free, unbound ion in solution that is called the ionic:
 - a. force.
 - b. potential.
 - c. activity.
 - d. action.
10. The predominant class of potentiometric electrodes used in the clinical laboratory is the:
 - a. gas-sensing electrode.
 - b. glass membrane electrode.
 - c. coulometric electrode.
 - d. polymer membrane ion-selective electrode.

Electrophoresis

Lindsay A.L. Bazydlo, James P. Landers

OBJECTIVES

1. Define the following:
 - Agarose
 - Ampholyte
 - Amphoteric
 - Blot/blotting
 - Densitometry
 - Electroendosmosis
 - Electrophoresis
 - Electrophoretic mobility
 - Polyacrylamide
 - Wick flow
2. State the theory of electrophoresis.
3. List and describe the components of an electrophoresis system, including buffers, support media, separation techniques, stains, and detection methods.
4. Identify the individual protein fractions of serum from an electropherogram.
5. Quantify the individual fractions of a scanned gel when given the total protein value.
6. Identify how each of the following affects electrophoresis: size and shape of molecule, heat and current produced by the power supply, buffer pH, and type of gel used.
7. Describe and compare the following types of electrophoretic techniques, including clinical utility, system components, and detection methods: (1) capillary, (2) isoelectric focusing, (3) microchip, (4) two-dimensional, and (5) zone.
8. Compare and contrast Southern, Northern, and Western blotting, including analyte, electrophoresis technique, and clinical utility.
9. State three advantages of capillary electrophoresis over conventional electrophoresis.
10. Explain how the following affect the performance of electrophoresis: endosmosis, buffer and stain integrity, sample type or appearance, and over-application or under-application of the sample.

KEY WORDS AND DEFINITIONS

Ampholyte A molecule that is positively or negatively charged on the basis of the pH of the solution in which it resides; proteins, because they contain many ionizable amino and carboxyl groups, behave as ampholytes in solution and are considered amphoteric.

Capillary electrophoresis A method in which the classic techniques of electrophoresis are carried out in a small-bore, fused silica capillary tube coated with a polymeric covering.

Densitometry A measuring technique that uses an optical system to scan and quantify electrophoretic fractions separated on a gel or other medium.

Electropherogram A densitometric display of protein zones on a support material after separation and staining.

Electrophoresis The migration of charged solutes or particles within a liquid medium under the influence of an electrical field.

Electrophoretic mobility (μ) The rate of migration (cm/s) of a charged solute in an electrical field, expressed per unit field strength (volts/cm).

Endosmosis (electroendosmotic flow) Preferential movement of water in one direction through an electrophoresis medium due to selective binding of one type of charge on the surface of the medium.

Isoelectric focusing An electrophoretic technique that separates amphoteric compounds within a medium that possesses a stable pH gradient.

Isoelectric point (pI) The pH at which a molecule has no net charge and will not migrate during electrophoresis.

Wick flow Movement of water from the buffer reservoirs toward the center of an electrophoresis gel or strip to replace water lost by evaporation.

Zone electrophoresis Migration of charged molecules in an applied electric field.

BASIC CONCEPTS

The first **electrophoresis** method used to study proteins was the free solution or moving boundary method devised by Tiseus in 1937. This technique was used in research to measure electrophoretic mobility and to study protein-protein interactions. It was able to resolve the serum proteins into only four component mixtures, with the α_1 fraction incompletely separated from albumin.

Zone electrophoresis can be performed in a porous supporting medium, such as agarose gel film, such that each protein zone is sharply separated from neighboring zones by a protein-free area. Zones are visualized by staining with a protein-specific stain to produce an **electropherogram**, which is then scanned and quantified using a densitometer. The support medium can also be handled after drying and kept as a permanent record. This is the most commonly applied technique in clinical chemistry and is used to separate proteins in serum, urine, cerebrospinal fluid (CSF), other physiologic fluids, erythrocytes and tissue, and nucleic acids in various tissue cells.

Although electrophoretic separation of biologically relevant macromolecules in gels (or paper) has been the workhorse of modern biomedical research, the advent of **capillary electrophoresis** (CE) has revolutionized separations. Intense interest in carrying out electrophoretic separation in capillaries with inner diameters ranging from 20 to 75 μm has resulted from its unprecedented resolving power, separation speed, and small sample analysis capabilities. However, the true significance of CE to the separations community can be seen in its ability to apply these separation principles in a multimodal approach to a variety of analytes that obviously included proteins and polynucleic acids, but also peptides, small drug-like molecules, and even ions.

POINTS TO REMEMBER

Electrophoresis

- Refers to the migration of ions in an electrical field
- Separation occurs based on the inherent electrophoretic mobility of an analyte
- Electrophoretic mobility is directly proportional to the net charge and inversely proportional to the size of the molecule and the viscosity of the electrophoresis medium

THEORY OF ELECTROPHORESIS

Depending on the charge they carry, ionized solutes move toward either the cathode (negative electrode) or the anode (positive electrode) in an electrophoresis system. For example, positive ions (cations) migrate to the cathode, and negative ions (anions) to the anode. An **ampholyte** (a molecule that is either positively or negatively charged, formerly called a zwitterion) becomes positively charged in a solution that is more acidic than its isoelectric point (pI)^a and migrates toward the cathode. In a more alkaline solution, the ampholyte becomes

negatively charged and migrates toward the anode. Because proteins contain many ionizable amino ($-\text{NH}_2$) and carboxyl ($-\text{COOH}$) groups, and because the bases in nucleic acids may also be positively or negatively charged, they both behave as ampholytes in solution.

The rate of migration of ions in an electrical field depends on the factors listed in **Box 11.1**. The equation expressing the driving force in such a system is given by

$$F = (X)(Q) = \frac{(\text{EMF})(Q)}{d} \quad (11.1)$$

where F = the force exerted on an ion; X = the current field strength (V/cm) (i.e., voltage drop per unit length of medium); Q = the net charge on the ion; EMF = the electromotive force [voltage (V) applied]; and d = the length of the electrophoretic medium (cm).

Steady acceleration of the migrating ion is counteracted by a resisting force characteristic of the solution in which migration occurs. This force, expressed by Stokes' law, is

$$F' = 6\pi\eta v \quad (11.2)$$

where F' = the counter force; $\pi = 3.1416$; r = the ionic radius of the solute; η = the viscosity of the buffer solution in which migration is occurring; and v = the rate of migration of the solute = velocity (length [l] traveled per unit of time [cm/s]).

The force F' counteracts the acceleration that would be produced by F if no counter force were present, and the result of the two forces is a constant velocity. Therefore, when

$$F = F' \quad (11.3)$$

then

$$6\pi\eta = (X)(Q) \quad (11.4)$$

or

$$v/X = 1 \times d/t \times E = Q/6\pi\eta = \mu \quad (11.5)$$

where v/X is the rate of migration (cm/s) per unit field strength (E/cm), defined as the **electrophoretic mobility** and expressed by the symbol μ .

Electrophoretic mobility is directly proportional to the net charge and is inversely proportional to the size of the molecule and the viscosity of the electrophoresis medium. Mobility may be positive or negative, depending on whether a protein migrates in the same or the opposite direction as the electrophoretic field (defined as extending from the anode to the cathode).

In addition to the factors listed in **Box 11.1**, other factors that affect electrophoretic mobility include electroendosmosis (endosmosis) and wick flow. Electroendosmosis affects mobility by causing uneven movement of water through the support medium. An electrophoretic support medium, such as a gel in contact with water, takes on a negative charge caused by the adsorption of hydroxyl ions. These ions are fixed to the surface and are immobile. Positive ions in solution cluster about the fixed negative charge sites, forming an ionic cloud of mostly positive ions. The number of negative ions in the solution increases with increasing distance from

^a The isoelectric point of a molecule is the pH at which it has no net charge and will not move in an electrical field.

Fig. 11.1 Distribution of + and - ions around the surface of an electrophoretic support. Fixed on the surface of the solid is a layer of - ions. A second layer of + ions is attracted to the surface. These two layers compose the Stern potential. The large, diffuse layer containing mostly + ions is the electrokinetic or zeta potential. Extending farther from the surface of the solid is homogeneous solution. The Stern potential plus the zeta potential equals the electrochemical potential, or epsilon potential.

the fixed negative charge sites until eventually positive and negative ions are present in equal concentrations (Fig. 11.1).

When current is applied to such a system, charges attached to the immobile support remain fixed, but the cloud of ions in solution moves to the electrode of opposite polarity. Because ions in solution are highly hydrated, this results in movement of the solvent as well. Movement of solvent and its solutes relative to the fixed support is referred to as **endosmosis** and causes preferential movement of water in one direction. Macromolecules in solution that move in the direction opposite this flow may remain immobile or may even be swept back toward the opposite pole if they are insufficiently charged. In media in which endosmosis is strong, such as conventional cellulose acetate and unpurified agarose gel, γ -globulins are swept back from the application point. Because the inner surface of a glass capillary contains many such charged groups, endosmosis is very strong and is actually the primary driving force for migration in CE systems. However, the endosmosis

in CE can be manipulated to modify the magnitude of the endosmotic effect. In electrophoretic media in which surface charges are minimal (starch gel, purified agarose gel, or polyacrylamide gel), endosmosis is minimal.

Wick flow results from the movement of buffer into the support medium. During electrophoresis, heat evolved because of the passage of current through a resistive medium can cause evaporation of solvent from the electrophoretic support. This drying effect draws buffer into the support, and, if significant, the flow of buffer can affect protein migration and hence the calculated mobility.

CLINICAL ELECTROPHORESIS

In this section, focus will be on the electrophoresis methodology that is frequently used in the clinical laboratory. Refer to Chapter 18 for a thorough discussion on the various electrophoretic fractions present in clinical protein electrophoresis.

Slab Gel Electrophoresis

Traditional methods, using a rectangular gel regardless of thickness, are referred to collectively by the term *slab gel electrophoresis*. Its main advantage is its ability to simultaneously separate several samples in one run. Starch, agarose, and polyacrylamide media have all been used in this format. It is the primary method used in clinical chemistry laboratories for the separation of various classes of serum or CSF proteins and DNA and RNA fragments. Gels (usually agarose) may be cast on a sheet of plastic backing or completely encased within a plastic-walled cell, which allows horizontal or vertical electrophoresis and submersion for cooling, if necessary.

General Operations

General operations performed in conventional electrophoresis include separation, detection, and quantification, as well as a number of "blotting" techniques.

Electrophoretic Separation

When electrophoresis is performed on precast microzone agarose gels, the following steps are typical: (1) excess buffer is removed from the support surface by blotting, taking care that bubbles are not present; (2) 5 to 7 μ L of sample is applied using a comb or a plastic template and is allowed to diffuse into the gel; it is then blotted to remove the excess; (3) the gel is placed into the electrode chamber; (4) electrophoresis is performed at specified current, voltage, or power; (5) the gel is fixed, rinsed, and then dried; (6) the gel is stained and redried; and (7) the gel is scanned in a densitometer. If isoenzymes are to be determined, substrate dye solution is incubated on the gel to stain zones before fixing and drying. Alternative procedures would be required if the more sophisticated methods described later are used.

Detection and Quantification

Once separated, proteins may be detected by staining followed by quantification using a densitometer, or by direct measurement using an optical detection system.

TABLE 11.1 Suggested Wavelengths for Quantitation of Protein Zones by Direct Densitometry

Separation Type	Stain	Nominal Wavelength, nm
Serum proteins in general	Amido Black (Naphthol Blue Black)	640
	Coomassie Brilliant Blue G-250 (Brilliant Blue G)	595
	Coomassie Brilliant Blue R-250 (Brilliant Blue R)	560
	Ponceau S	520
Isoenzymes	Nitrotetrazolium Blue	570
Lipoprotein zones	Fat Red 7B (Sudan Red 7B)	540
	Oil Red O	520
	Sudan Black B	600
DNA fragments	Ethidium bromide (fluorescent)	254 (Ex)
		590 (Em)
CSF proteins	Silver nitrate	—

CSF, Cerebrospinal fluid; Em, emission; Ex, excitation.

Staining. If staining is used to visualize separated proteins, the proteins usually are fixed first by precipitating them in the gel with a chemical agent such as acetic acid or methanol. This prevents diffusion of proteins out of the gel when submersed in the stain solution. The amount of dye taken up by the sample is affected by many factors, such as the type of protein and the degree of denaturation of the proteins by fixing agents.

Table 11.1 lists dyes commonly used in electrophoresis, along with suggested wavelengths for quantification by **densitometry**. Most commercial methods for serum protein electrophoresis use Amido Black B or members of the Coomassie Brilliant Blue series of dyes for staining. Isoenzymes are typically visualized by incubating the gel in contact with a solution of substrate, which is linked structurally or chemically to a dye before fixing. Silver nitrate stains proteins and polypeptides with sensitivity 10- to 100-fold greater than that of conventional dyes. Selective fixing and staining of protein subclasses can also be achieved by combining a stain molecule with an antiglobulin, as is done in IFE.

Improvements in conducting sensitive measurements have been achieved by linking an enzyme, such as alkaline phosphatase or peroxidase, to a single or double antibody specific for particular proteins, such as oligoclonal immunoglobulin (Ig), or by spraying separated proteins with luminal and peroxide to develop chemiluminescence, which, in turn, exposes x-ray film to form a permanent image. Chemiluminescence has been used in this way to quantify IgE, and DNA fragments have been detected by linking with a fluorescent dye label.

In practice, a typical stain solution may be used several times before it is replaced. A good rule of thumb is that a stain solution of 100 mL may be used for a combined total of 387 cm² (60 in²) of agarose film. The stain solution may be

considered faulty if leaching of stained protein zones occurs in the 5% acetic acid wash solution. Whenever protein zones appear too lightly stained, the stain or substrate reagent—in the case of isoenzymes—should always be suspected. Stain solution must be stored tightly covered to prevent evaporation.

Quantification. A *densitometer* is used to quantify stained zones. This instrument measures the absorbance of each fraction as the gel (or other medium) is moved past a photometric optical system and displays an electropherogram on a computer display. The software is able to automatically integrate the area under each peak and report each as a percent of total or as absolute concentration or activity computed from the total protein or activity of enzyme in the sample.

Reliable densitometric quantification requires: (1) light of an appropriate wavelength; (2) linear response from the instrument; and (3) a transparent background in the medium being scanned. Linearity may be tested with a neutral density filter designed with separated or adjacent areas of linearly increasing density. The densities are permanent and have expected absorbance values. The very small sample sizes used and the transparency of agarose gels satisfy the requirement for a clear background. Nevertheless, problems can occur with densitometry because of differences in the quantity of stain taken up by individual proteins and differences in protein zone sizes.

Essential features of a densitometer include: (1) the ability to scan gels 25 to 100 mm in length; (2) electronic adjustment of the most intense peak to full scale; (3) automatic background zeroing (peaks are not lost or “cut off”); (4) variable wavelength control over the range of 400 to 700 nm; (5) variable slits to allow adjustment of the beam size; (6) an integrating device with both automatic and manual selection of cut points between peaks; and (7) automatic indexing, a feature that advances the electrophoresis strip from one sample channel to the next.

Desirable features of a densitometer include computerized integration and printout, built-in diagnostics for instrument troubleshooting, the choice of one of several scanning speeds, and the ability to measure in the reflectance mode. Models with a separate computer for data processing permit storage and reformatting of data, if desired, and reprinting or delayed transmission to a host computer.

DNA analysis requires the ability to scan larger gels, which may contain several dozen bands of DNA fragments of different length. Modern automated electrophoresis systems also use larger gels containing 30 or more samples, which are scanned on a new generation of densitometers referred to as *flatbed scanners* or *digital image analyzers*. These instruments are capable of scanning and storing digitized light intensity readings from large areas and use ultrasensitive charge-coupled device detectors having a resolution of up to 1200 dots per inch (21 μ m). Sophisticated data processing software permits manipulation of stored image information to produce conventional scans and computations or more complex outputs, such as overlaying and subtraction of patterns from two different samples.

Fig. 11.2 A schematic diagram of a typical electrophoresis apparatus showing two buffer boxes with: (1) baffle plates, (2) electrodes, (3) electrophoretic support, (4) wicks, (5) cover, and power supply.

Blotting Techniques

In 1975, Edward Southern developed a technique that is widely used to detect fragments of DNA. This technique, known as *Southern blotting*, first requires electrophoretic separation of DNA or DNA fragments by agarose gel electrophoresis (AGE). Next, a strip of nitrocellulose or a nylon membrane is laid over the agarose gel, and the DNA fragments are transferred or “blotted” onto it by capillary, electro, or vacuum blotting. They are then detected and identified by hybridization with a labeled, complementary nucleic acid probe. This technique is widely used in molecular biology for identifying a particular DNA sequence; determining the presence, position, and number of copies of a gene in a genome; and typing DNA.

Northern and *Western* blotting techniques, named by analogy to Southern blotting, were subsequently developed to separate and detect ribonucleic acids (RNAs) and proteins, respectively. Northern blotting is carried out identically to Southern blotting except that RNA species are separated by electrophoresis. Western blotting is used to separate, detect, and identify one or more proteins in a complex mixture. It involves first separating the individual proteins by polyacrylamide gel and then transferring or “blotting” onto an overlying strip of nitrocellulose or a nylon membrane by electro-blotting. The strip or membrane is then reacted with a reagent that contains an antibody raised against the protein of interest.

Instrumentation

Although modern electrophoresis equipment and systems vary considerably in form and degree of automation, the essential components common to all systems (Fig. 11.2) include: (1) two reservoirs that contain the buffer used in the process, (2) a means of delivering current from a power supply via platinum or carbon electrodes contacting the buffer, and (3) a support medium in which separation takes place connecting the two reservoirs. In some systems, wicks may connect the medium to the buffer solution or directly to the electrodes. The entire apparatus is enclosed to minimize evaporation and protect both the system and the operator. The direct current power supply sets the polarity of the electrodes and delivers current to the medium.

Power Supplies

The power supply drives the movement of ionic species in the medium and allows adjustment and control of the current or

the voltage. With more sophisticated units, the power may be controlled as well, and conditions may be programmed to change during electrophoresis. Capillary systems use power supplies capable of providing voltages in the kilovolt range.

Current flowing through a medium that has resistance produces heat:

$$\text{Heat} = (E)(I)(t) \quad (11.6)$$

where E = electromotive force (EMF) in volts (V); I = current in amperes (A); and t = time in seconds (s).

This heat is released into the medium and increases the thermal agitation of all dissolved ions, and therefore the conductance of the system (decreases resistance). With constant-voltage power supplies, the resultant rise in current increases both protein migration and evaporation of water from the medium. Any water loss increases the ion concentration and further decreases the resistance (R). Under these circumstances, the current and therefore the migration rate will progressively increase. To minimize these effects, it is best to use a constant-current power supply. According to Ohm's law,

$$E = (I)(R) \quad (11.7)$$

therefore if R decreases, the applied EMF also decreases, keeping the current constant. This in turn decreases the heat effect and stabilizes the migration rate.

Buffers

Buffer ions have a twofold purpose in electrophoresis: they carry the applied current, and they fix the pH at which electrophoresis is carried out. Thus they determine: (1) the type of electrical charge on the solute, (2) the extent of ionization of the solute, and therefore (3) the electrode toward which the solute will migrate. The buffer's ionic strength determines the thickness of the ionic cloud (buffer and non-buffer ions) surrounding a charged molecule, the rate of its migration, and the sharpness of the electrophoretic zones. With increasing concentration of ions, the ionic cloud increases in size, and the molecule becomes more hindered in its movement.

According to Joule's law, power produced when current flows through a resistive medium is dissipated as heat. This heat increases in direct proportion to the resistance, but also in proportion to the square of the current. The reduction in resistance caused by a high ionic strength buffer therefore leads to increased current and excessive heat. These buffers yield sharper band separations, but the benefits of sharper resolution are diminished by the Joule (heat) effect that leads to denaturation of heat-labile proteins or the degradation of other components.

Ionic strength (also denoted by the symbol μ) is computed according to the following:

$$\mu = 0.5 \sum c_i z_i^2 \quad (11.8)$$

where c_i = ion concentration in mol/L and z_i = the charge on the ion.

The ionic strength μ of an electrolyte (buffer) composed of monovalent ions is equal to its molarity (mol/L). The ionic

strength of a 1 mol/L electrolyte solution with one monovalent and one divalent ion is 3 mol/L, and for a doubly divalent electrolyte, it is 4 mol/L.

A relatively high ionic strength buffer used in *high-resolution electrophoresis* improves the separation of serum proteins into as many as 13 bands, with two or more bands in the α_1 , α_2 , and β -globulin regions and one or more additional bands seen in various pathologic conditions. Because of higher conductivity and the associated heat produced, it is necessary to reduce the temperature of the system to 10°C to 14°C. "Submarine" techniques, in which gels are submersed in circulating buffer cooled by an external cooling device, or are supported on an electrophoresis chamber cooled by circulating water or an integral Peltier plate, provide exact temperature control. Effective cooling with less precise temperature control may also be achieved using chambers designed with a sealed compartment of cooled ethylene glycol, which is in contact with the gel during running.

Because buffers used in electrophoresis are good culture media for the growth of microorganisms, they should be refrigerated when not in use. Moreover, a cold buffer is preferred in an electrophoretic run, because it improves resolution and decreases evaporation from the electrophoretic support. Buffer used in a small-volume apparatus should be discarded after each run because of pH changes resulting from the electrolysis of water that accompany electrophoresis. If volumes used are larger than 100 mL, buffer from both reservoirs may be combined, mixed, and reused up to four times.

Support Media

The support medium provides the matrix in which protein separation takes place. Various types of support media have been used in electrophoresis and range from pure buffer solutions in a capillary to insoluble gels (e.g., sheets, slabs, or columns of starch, agarose, or polyacrylamide) or membranes of cellulose acetate. Gels are cast in a solution of the same buffer to be used in the procedure and may electrophorese in a horizontal or vertical direction. In either case, maximum resolution is achieved if the sample is applied in a very fine starting zone. Separation is based on differences in charge-to-mass ratio of the proteins and, depending on the pore size of the medium, possibly molecular size.

Cellulose Acetate. Cellulose acetate, a thermoplastic resin made by treating cellulose with acetic anhydride to acetylate the hydroxyl groups, is primarily of historical interest. When dry, the membranes contain about 80% air space within the interlocking cellulose acetate fibers and are opaque, brittle films. As the film is soaked in buffer, the air spaces fill with liquid, and it becomes pliable. Samples are applied with a twin-wire applicator or the edge of a glass slide. Because of their opacity, stained membranes need to be made transparent (cleared) for densitometry by soaking in 95:5 methanol:glacial acetic acid. Cleared membranes are strong and could be stored as a permanent record, but because of the necessity for presoaking and clearing, cellulose acetate has largely been replaced by agarose in most clinical applications.

Agarose. Agarose is a linear polymer containing alternating D-galactose and 3,6-anhydro-L-galactose monomers. It is the purified, essentially neutral fraction of agar obtained by separating agarose from agaropectin, a more highly charged fraction containing acidic sulfate and carboxylic side groups. Because the pore size in agarose gels is large enough for all proteins to pass through unimpeded, separation is based only on the charge-to-mass ratio of the protein. Advantages of agarose gel include its low affinity for proteins and its native clarity after drying, which permits excellent densitometry. It is essentially free of ionizable groups and so exhibits little endosmosis.

Most routine procedures for AGE are now performed using commercially produced, prepackaged microzone gels, and the sample is applied by means of a comb or a thin plastic template, with small slots corresponding to sample application points. The template is placed on the agarose surface, and 5 to 7 μ L samples are placed on each slot. The serum sample is allowed to diffuse into the agarose for 5 minutes, the excess sample is removed by blotting, and the template is removed. AGE separation for most routine serum applications requires an electrophoresis time of 20 to 30 minutes.

Polyacrylamide Gel. Polyacrylamide is a polymeric matrix consisting of linear chains of acrylamide cross-linked with bis-acrylamide. It is thermostable, transparent, strong, and relatively chemically inert, and—depending on concentration—can be made in a wide range of pore sizes. Its average pore size in a typical 7.5% gel is about 5 nm (50 Å), which is large enough to allow most serum proteins to migrate unimpeded. However, proteins with a molecular radius and/or length that exceeds critical limits will be impeded in their migration. Some of these proteins are fibrinogen, β -lipoprotein, α_2 -macroglobulin, and γ -globulins; a schematic representation of serum protein electrophoresis by polyacrylamide gel electrophoresis (PAGE) is shown in Fig. 11.3. The separation is based on both charge-to-mass ratio and molecular size (a phenomenon referred to as *molecular sieving*), and serum proteins can be resolved into more individual fractions than with an agarose gel. Furthermore, these gels are uncharged, thus eliminating electroendosmosis. Precast minigels are available in a variety of concentrations and acrylamide-to-bis-acrylamide ratios suitable for most protein or nucleic acid separations. However, because of the known neurotoxicity of acrylamide, appropriate caution must be exercised when handling this material if the gels are prepared by hand.

Fig. 11.3 A simplified schematic drawing of a protein pattern from the serum of a subject with haptoglobin type 2-1 (separation by polyacrylamide gel electrophoresis). Some zones contain more than the one protein shown, as demonstrated by immunologic techniques. AAT, α_1 -Antitrypsin; ALB, albumin; AMG, α_2 -macroglobulin; BLP, β -lipoprotein; C3, complement 3; FIB, fibrinogen; Gamma, γ -globulin; HP, haptoglobin; TRF, transferrin.

Attempts to improve the hydrophilic nature of polyacrylamide have led to the development of mono- and di-substituted monomers, one of which is *N*-acryloyl-tris(hydroxymethyl)aminomethane, or Poly(NAT). This material is more hydrophilic than polyacrylamide, and its matrix has larger pores, thereby presenting less resistance to the passage of large molecules. It is ideally suited to the separation of DNA fragments up to 20 kilobases (kb) in size using a homogeneous (non-pulsed) electric field. Fragments that differ in size by as little as 2% can be resolved. Gels are submerged in buffer during use, allowing temperatures to be tightly controlled at values between 50°C and 60°C. Use of increased temperatures results in shorter run times and more reproducible band migration.

Automated Systems

Because of increased volume of testing, primarily for serum proteins, many laboratories are converting to automated systems for electrophoresis. Such a system is the Helena SPIFE 4000 (Helena Laboratories, Beaumont, TX), an automated electrophoresis system providing automated reagent application and a variety of gel sizes that permit analysis of 10 to 100 samples simultaneously. It also features in-line sample application, automated electrophoretic separation and staining of analytes, multiple stain ports, and positive sample identification. The Interlab Microgel system (Interlab Srl, Rome, Italy) also fully automates the process and integrates sample application, temperature-controlled electrophoresis, staining, and densitometry into a single unit with the capability of managing four gels simultaneously. Other systems that have partially automated the procedure or incorporated the ability to process sequentially multiple gels of different compositions include the Phast System (Pharmacia LKB, Gaithersburg, MD), the HITE Fractoscan (Olympus, Invicon, München, Germany), the Hydragel-Hydrasys (Sebia Inc., Durham, NC), and the High-Performance Gel Electrophoresis (HPGE)-1000 system (LabIntelligence Inc., Belmont, CA). Most CE systems (see “Capillary Electrophoresis” section) have autosampling capability for sequentially processing specimens, but the Sebia CAPILLARYS permits simultaneous processing of seven samples by using multiple capillaries. Newer microchip-based analyzers like the Agilent 2100 Bioanalyzer (Agilent Technologies Inc., Santa Clara, CA) significantly miniaturize and increase the speed of the process for separating proteins, nucleic acids, or even entire cells. These advances substantially reduce the labor component associated with electrophoresis.

POINTS TO REMEMBER

Capillary Zone Electrophoresis

- Uses electroosmotic flow (EOF) to mobilize the sample plug pass the detector
- The magnitude and direction of EOF can be manipulated through methodology
- Higher voltages can be applied due to more efficient dissipation of heat; this can translate to faster separations

CAPILLARY ELECTROPHORESIS

With CE, classic techniques of are carried out in a small-bore (10- to 100- μ m internal diameter) fused silica capillary tube, 20 to 200 cm in length.

Two distinct advantages of the capillary format include the ability to apply much higher voltages than in traditional electrophoresis and the ease of automation. Applications are also more extensive and include the separation of low molecular weight ions in addition to proteins and other macromolecules. Even uncharged molecules can be separated using CE in the micellar electrokinetic chromatography (MEKC) mode discussed later. CE has also proved useful for separation of inorganic ions, amino acids, organic acids, drugs, vitamins, porphyrins, carbohydrates, oligonucleotides, proteins, and DNA fragments.

General Operations

A schematic diagram of a typical instrumental configuration for CE is shown in Fig. 11.4. As indicated, the capillary serves as an electrophoretic chamber, analogous to a lane on a gel, which is connected to buffer reservoirs at both ends, which, in turn, are connected to a high-voltage power supply. It is important to note that at some point along the length of the capillary (typically close to the end), a detector is interfaced for online detection. Improved heat dissipation from the capillary (as opposed to a slab gel) permits the application of voltages in the range of 10 to 30 kV, which enhances separation efficiency and reduces separation time—in some cases to less than 1 minute. Only a few microliters of the sample are required, with injected volumes in the nanoliter range. The small sample plug volume minimizes distortions in the applied field caused by the presence of analytes or other sample species.

In contrast to the cumbersome and time-consuming tasks of conventional electrophoresis, CE is easily automated. Analogous to high-performance liquid chromatography (HPLC) technology, samples typically are stored in a temperature-controlled environment and are automatically injected into the capillary, with a variety of detector types available; the resulting electropherograms are analyzed and manipulated in much the same manner as chromatograms.

Fig. 11.4 A schematic for capillary electrophoresis instrumentation.

The capillaries used as separation columns in CE are most commonly made from fused silica (i.e., pure glass) coated with a thin exterior covering of polyimide to provide strength and flexibility. Although capillaries can be made from other materials, such as polyethylene or Teflon, such capillaries have seen limited use. The polyimide coating is usually removed from a small portion of the capillary close to the terminal end, creating a window for online optical detection. The outer diameter of the capillary tubing typically varies from 180 to 375 μm , the inner diameter from 20 to 180 μm , and the total length from 20 cm up to several meters. Noncylindrical capillary tubing suitable for CE is now available from some commercial providers. For example, rectangular capillaries (Polymicro Technologies, Phoenix, AZ) provide a flat surface that is more amenable to optical detection than that of their curved counterparts.

CE is distinguished from other forms of electrophoresis by the fact that extraordinarily high voltage (30,000 volts) has been used to obtain rapid, high-efficiency separations. The problems encountered with noncapillary platforms (e.g., slab gels) are avoided because of the effective dissipation of Joule heat by forced air convection or liquid cooling of the narrow-bore capillary.

Sample Injection

In CE, sample volumes of 1 to 50 nL are loaded into the capillary by *hydrodynamic injection* or *electrokinetic (EK) injection*. With hydrodynamic injection, an aliquot of a sample is introduced by applying positive pressure at the inlet vial or vacuum at the outlet vial. The volume of sample loaded is governed by a number of parameters, including (but not restricted to): (1) the inner diameter of the capillary; (2) buffer viscosity; (3) applied pressure; (4) temperature; and (5) time. With some earlier commercial or homemade systems, gravity was used as the source of pressure by raising the inlet vial (or lowering the outlet vial), thus allowing “siphoning” to occur for a timed interval. With EK injection, an aliquot of a sample is introduced by applying a voltage for a timed interval. The magnitude of the voltage is dependent on the analyte and buffer system used but typically involves field strengths three to five times lower than that used for separation. It is important to note that although hydrodynamic methods introduce a sample representative of the bulk specimen, EK injection favors the preferential movement of more electrokinetically mobile analytes into the capillary.

In practice, to maintain high separation efficiency, the sample plug length is usually less than 2% of the total capillary length.

Direct Detection

With CE, separated analytes are detected and measured as they migrate past a point on the capillary that is optically interrogated. Optical detection is based on classical methods, such as photometric absorbance, refractive index, and fluorescence (see Chapter 9). As with HPLC, ultraviolet-visible photometers are widely used as detectors to monitor CE separations. To interface such online detectors with the capillary,

a detection window is created toward the outlet end of the capillary. This “window,” which serves as an inline cuvette, typically is formed by burning off the polyimide with a small flame and cleaning the window with ethanol. Although this configuration allows high-efficiency separation, the inner diameter of the capillary tube defines the optical path length (OPL) of the inline cuvette. Because absorbance is directly proportional to the length of the cuvette used in an optical system, the 20 to 100 μm inner diameter of the capillary limits UV-visible absorbance detection limits to concentrations of 10^{-8} to 10^{-6} molar.

More sensitive optical techniques that have been used with CE include: (1) fluorescence; (2) refractive index; (3) chemiluminescence; (4) Raman spectrophotometry; and (5) circular dichroism. The most sensitive optical detection method used in CE is laser-induced fluorescence, which is capable of detection limits in the 10^{-9} to 10^{-12} molar (or better) range. This detection mode is easily accomplished with analytes that may be easily labeled with a fluorescent substrate (e.g., intercalators for double-stranded DNA) or may be naturally fluorescent (e.g., proteins or peptides containing tryptophan). CE systems have also been interfaced with mass spectrometers, and electrochemical detection methods have been developed, although such detectors must be isolated electrically from the electrophoretic voltages.

Indirect Detection

When strong chromophores are lacking in the analyte of interest, absorbance and fluorescence detection have been used in an indirect mode. In this mode, a strongly absorbing ion is added to the running electrolyte and is monitored at a wavelength that gives a constant, high background absorbance. As solute ions move into their discrete zones during the electrophoretic process, they displace the indirect detection agent through mutual repulsion, and this produces a decrease in background absorbance as the zone passes through the detector. Reagents with appropriate fluorescence properties have been used in a similar manner. Indirect detection of amino acids by CE has been demonstrated, with the potential for use in the diagnosis of amino acidurias. Investigators have demonstrated the direct extrapolation of this technique to microchip detection when UV detection is difficult, if not impossible.

TYPES OF ELECTROPHORESIS

Capillary Zone Electrophoresis

CZE, also called *open-tube* or *free-solution* CE, is the simplest form of CE. It includes *capillary ion electrophoresis*, which refers to the analysis of inorganic ions by CZE, often using indirect detection. The power of the CZE mode is its ability to electrophoretically resolve charged species without a sieving matrix; this applies to a broad spectrum of analytes ranging from proteins, peptides, and amino acids to small molecules (e.g., drugs) and ions.

Capillary Gel Electrophoresis

Capillary gel electrophoresis (CGE) is directly comparable with traditional slab or tube gel electrophoresis because the

separation mechanisms are identical. Size separation is achieved with a suitable polymer, which acts as a molecular sieve or sizing mechanism. As charged analytes migrate through the polymer network, they become hindered to a degree that is governed by their size (larger molecules are hindered more than smaller ones). Macromolecules, such as DNA and sodium dodecyl sulfate (SDS)-saturated proteins, cannot be separated without a gel or some other separation mechanism, because they have a mass-to-charge ratio that is size independent. The term *gel* in CGE is a misnomer, primarily because cross-linked “gels,” as we know them in slab format, are not routinely used in CE. A more suitable term is a *sieving matrix* or *soluble polymer network*, a linear polymeric structure that is soluble, has reasonably low viscosity, and is capable of self-entangling in a manner that forms pores through which sieving can occur. A variety of polymeric matrices have been defined for DNA (e.g., polyacrylamide, cellulosic materials) and protein analysis (e.g., dextran-base matrices), provided that pores can be formed inherently that have diameters in the range of tens to hundreds of nanometers. One of the requirements that often accompany this type of analysis is reduction of electro-osmotic flow. This is accomplished by covalently, adsorptively, or dynamically coating the surface. Cross-linked polyacrylamide was the main polymer of choice for this but recently has been supplanted by a host of polymeric matrices that not only provide effective molecular sieving but also adsorptively coat the capillary surface.

TECHNICAL CONSIDERATIONS

Gel

In performing electrophoretic separations, a number of technical and practical aspects need to be considered, as they affect the process.

Sampling

To achieve a proper balance between sensitive measurements and resolution, the amount of serum protein applied to an electrophoretic support must be optimum. Albumin is about 10 times more concentrated in serum than the smallest fraction, the α_1 -globulins. Therefore, the amount of serum applied should prevent overloading with albumin, but should still be adequate to quantify α_1 -globulin. For the separation of serum proteins using PAGE, 3 μ L of serum containing approximately 210 μ g of total protein is applied. For alkaline phosphatase isoenzymes, up to 25 μ L of a normal serum may be applied (less may be used if activity is greatly increased). Urine specimens require 50- to 100-fold greater concentrations or extended application times for adequate sensitivity, and CSF may or may not require concentration, depending on the staining approach used.

Discontinuities in Sample Application

Discontinuities in sample application may be caused by: (1) dirty applicators; (2) uneven absorption by sample combs; or (3) inclusion of an air bubble if the sample is pipetted onto the gel. The pipette tip should be checked for air bubbles before the sample is applied to the agarose gel template.

Unequal Migration Rates

Unequal migration of samples across the width of the gel may be caused by dirty electrodes, which may cause uneven application of the electric field, or by uneven wetting of the gel. If wicks are used to connect the gel to a power supply, uneven wetting of the wicks could cause unequal migration or bowing of sample lanes at the gel edges. Gels must be kept horizontal during storage to avoid sagging and uneven thickness. Finally, gels that may have been stored too close to heat sources (e.g., in a cabinet over a light fixture) could have partially and unevenly dried areas, contributing to similar problems.

Distorted, Unusual, or Atypical Bands

Distorted protein zones may be caused by: (1) bent applicators; (2) incorporation of an air bubble during sample application; (3) over-application; or (4) inadequate blotting of the sample. Excessive drying of the electrophoretic support before or during electrophoresis may also cause distorted zones. Irregularities (other than broken zones) in the sample application probably are due to excessively wet agarose gels. Portions of applied samples may look washed out.

In most cases, unusual bands are artifacts that may be easily recognized. Hemolyzed samples are frequent causes of increased β -globulin (where free hemoglobin migrates) or an unusual band between the α_2 - and β -globulins, the result of a hemoglobin-haptoglobin complex. A band occurring at the starting point of an electropherogram may be fibrinogen. The sample should be verified as being serum before this band is reported as an abnormal protein. The α - and β -lipoproteins may migrate ahead of their normal positions in some samples. Occasionally, a split albumin zone is observed in the rare, benign, genetically related condition of bis-albuminemia. However, a grossly widened albumin zone could be due to albumin-bound medication and not to faulty electrophoresis.

Capillary

Temperature and surface effects influence the separation capabilities of CE. Artifacts also have been known to arise with CE.

Temperature Effects

In most slab or tube platforms for electrophoresis, moderate electric fields (up to 1000 volts) are used, because the Joule heating that accompanies the use of higher field strengths causes nonuniform temperature gradients, local changes in viscosity, and subsequent zone broadening. CE is distinguished from other forms of electrophoresis by the fact that extraordinarily high fields (30,000 volts) are used to obtain rapid, high-efficiency separations. The problems encountered with noncapillary platforms are prevented by effective dissipation of Joule heat by forced air convection or liquid cooling of the capillary, both of which are possible because of the narrow bore of the capillary. The Joule heat produced is a function of (1) buffer type, (2) concentration, (3) voltage applied, (4) capillary inner diameter, and (5) length, and can be determined

for any given system by generating an *Ohm's law plot*, which allows easy determination of the maximum voltage that can be used effectively. Reducing the inner diameter of the capillary, the ionic strength of the running buffer, or the applied voltage will reduce the heat produced by the electrophoretic process. It should be noted that reducing the inner diameter will compromise the detection limit of UV measurements (smaller OPL); reducing the applied field is less desirable in that resolution is directly proportional to the applied field. Consequently, attempts should be made to alter other parameters before reducing inner diameter or the applied field.

Surface Effects

As in electrophoresis in general, the flow of fluid (electro-osmotic or electroendosmotic flow [EOF]) in CE is a consequence of surface charge on the solid support. In CE, EOF can play a significant role in the separation process. The charge on the inner surface of a fused silica capillary is determined by the ionization state of the silanol groups (SiOH) that populate it. Interaction of positively charged buffer species with bound surface anions generates a layer of mobile cations that move toward the cathode when voltage is applied. This induces a very strong EOF that mobilizes all analytes in the same direction, regardless of their charge. Separation is consequently achieved because of differences in the electrophoretic migration rates of analytes superimposed on this EOF.

Because the driving force of the flow is distributed along the wall of the capillary, the flow profile is nearly flat or plug-like, contrasting with the laminar or parabolic flow generated by a pressure-driven system caused by shear forces at the wall. A flat flow profile is beneficial because it does not contribute to the dispersion of solute zones. The magnitude and direction of the EOF are influenced by several parameters, including: (1) type of electrolyte used; (2) pH; (3) ionic strength; (4) use of additives (e.g., surfactants, organic solvents); and (5) polarity and magnitude of the applied electric field.

Although advantageous for the dissipation of Joule heat, the large surface area-to-volume ratio of the inner capillary space increases the likelihood of analyte adsorption onto the surface of its inner wall. This causes phenomena such as peak tailing and even total and irreversible adsorption of the analyte. Adsorption is typically noted between cationic solutes and the negatively charged inner wall of the capillary, primarily through ionic interactions (with deprotonated silanols), but also involves hydrophobic interactions (with siloxanes). Because of the numerous charges and hydrophobic regions, significant adsorptive effects have been noted, especially for highly cationic proteins. In practice, adsorption of substances, whether from the sample or from the buffer, to the inner surface of the capillary will alter migration times and other separation characteristics; unaddressed, the capillary eventually may become "fouled." Buffer components and/or additives, such as surfactants, can often render permanent changes to the inner surface of the capillary (through adsorption) and may warrant dedication of specific capillaries for use with particular surfactants.

To minimize these inner wall effects, capillaries are conditioned by chemical treatment, most commonly with base, to

remove adsorbates and rejuvenate the surface. A typical wash method includes flushing the chamber with 10 to 20 capillary volumes of 0.1 to 1.0 mol/L NaOH, followed by flushing with "run" buffer. To prevent exposing the capillary surface to drastic fluctuations in pH, conditioning procedures for separations at low pH may be better served by using strong acids (e.g., HNO₃), surfactants (e.g., SDS), or organic solvents, such as acetonitrile or methanol.

Serum Protein Analysis. Compared with AGE and cellulose acetate electrophoresis (CAE), CZE is more advantageous for serum protein analysis. Fig. 11.5 shows a comparison of the separation of serum proteins by CAE, AGE, and CE. The presence of the classical zones with CE is apparent, albeit in reversed order, as is the identification of serum protein abnormalities in gamma regions. Retrospective studies have shown CE to be effective for detecting monoclonal proteins, which could then be immunotyped by conventional techniques (IFE and **isoelectric focusing** [IEF]). Moreover, CE can do both serum protein electrophoresis and immunotyping in hundreds of samples simultaneously. These and other studies put forth the same conclusion: that CE is more sensitive than AGE in identifying abnormalities. Furthermore, CZE can be used effectively in serum protein analysis.

Artifacts in Serum Protein Analysis. With CE using online optical detection, artifacts can occur in the form of "system peaks." These often originate from the sample or from the interfaces between the sample and the separation buffer, because any species that absorbs at the detection wavelength will generate a response. This differs from protein slab gel

Fig. 11.5 Rapid protein electrophoresis of serum protein; comparison with scanning densitometry profiles obtained from cellulose acetate (CAE) and agarose (AGE) electrophoresis. (A) Normal serum. (B) Patient serum containing a large M-protein. (C) Patient serum containing a small monoclonal protein. Arrows indicate the position of the monoclonal proteins. CZE, Capillary zone electrophoresis.

electrophoresis, wherein detection specificity is governed by a protein-specific stain. It is not uncommon, for example, for buffer species present in the sample but not in the separation buffer to generate system peaks.

One problem associated with conventional electrophoresis of serum proteins is its proclivity for point-of-application artifacts. These are bands that result from the fact that electrophoretic mobility (e.g., with AGE) is bidirectional from the point of application. These precipitates may be euglobulin or cryoprecipitates and may or may not contain a monoclonal protein; only immunoelectrophoresis or IFE can identify the presence of monoclonal proteins. These bands must be immunotyped to distinguish real monoclonal proteins from artifacts—a process that is costly and time-consuming. CE prevents point-of-application artifacts in two ways. First, net mobility in CE results from the vectorial addition of both protein electrophoretic mobility and EOF. As a result of this unidirectional movement (toward the detector), the point of application remains removed from the detector. Second, unlike AGE, where precipitates cannot exit the loading well and enter the gel (thus appearing as a band in the scanned region of the gel), no gel matrix is present in CZE to impede electrophoretic migration because analysis occurs in free solution.

Improving Limits of Detection. Several approaches have been devised to improve the limit of detection of online CE detectors. These include increasing the length of the OPL and online concentration of the sample.

Increased Optical Path Length. Capillary tubes modified at the detector window with a “bubble” cell (a glass-blown expansion of the internal diameter of the capillary tube) can expand the OPL by almost an order of magnitude, with concomitant lowering of the system’s limit of detection. Alternatively, a “Z” geometry has been developed that increases the OPL via detection down the core of the capillary, with possible lengths up to 1 mm.

Online Sample Concentration. Another technique used in CE systems to increase their limit of detection is preconcentration of the sample. One of the simplest methods for sample preconcentration is to induce a “stacking” effect with the sample components, which is easily accomplished by exploiting the ionic strength differences between the sample matrix and the separation buffer. This results from the fact that sample ions have decreased electrophoretic mobility in a higher conductivity environment. When voltage is applied to the system, sample ions in the sample plug instantaneously accelerate toward the adjacent separation buffer zone. Upon crossing the boundary, the higher conductivity environment induces a decrease in electrophoretic velocity and subsequent “stacking” of the sample components into a smaller buffer zone than the original sample plug. Within a short time, the ionic strength gradient dissipates and the charged analyte molecules begin to move from the “stacked” sample zone toward the cathode. Stacking has been used with hydrostatic or EK injection and typically yields a tenfold enhancement in sample concentration, resulting in a lower limit of detection.

An alternative approach to stacking is “focusing,” which is based on pH differences between the sample plug and the

separation buffer. This is very useful for the analysis of peptides, mainly because of their relative stability over a wide pH range. By increasing the pH of the sample to above that of the net pI of the analytes of interest and flanking the sample plug with low pH separation buffer zones (i.e., an equivalent volume of low pH separation buffer following introduction of the sample plug), negatively charged peptides are electrophoretically driven toward the anode. Upon entering the lower pH separation buffer, a pH-induced change in their charge state causes a reversal in their electrophoretic mobility, resulting in “focusing” of the peptides at the interface of the sample (high pH) and low pH buffer plugs (similar to those in isoelectric focusing). After the pH gradient dissipates, the peptides, again positively charged, migrate toward the cathode as a sharp zone. This approach has been applied to a variety of analytes, but it is limited to those that are able to withstand inherent changes in pH without substantial denaturation, and may yield as much as a five-fold enhancement of a system’s limit of detection.

SPECIALITY ELECTROPHORESIS TECHNIQUES

Isoelectric Focusing Electrophoresis

IEF separates amphoteric compounds, such as proteins, with increased resolution in a medium possessing a stable pH gradient. The protein becomes “focused” at a point on the gel as it migrates to a zone where the pH of the gel matches the protein’s pI. At this point, the charge of the protein becomes zero, and its migration ceases. Fig. 11.6 illustrates the procedure and shows the electrophoretic conditions before and after current is applied. The protein zones are very sharp, because the region associated with a given pH is very narrow. Ordinary diffusion is also counteracted by the acquisition

Fig. 11.6 Schematic of an isoelectric focusing procedure. (I) A homogeneous mixture of carrier ampholytes, pH range 3 to 10, to which proteins A, B, and C, with isoelectric points (pI) of 8, 6, and 4, respectively, were added. (II) Current is applied and carrier ampholytes rapidly migrate to pH zones where the net charge is zero (the pI value). (III) Proteins A, B, and C migrate more slowly to their respective pI zones, where migration ceases. The high buffering capacity of the carrier ampholyte creates stable pH zones in which each protein may reach its pI.

of a charge, as a protein varies from its pI position and subsequently migrates back because of electrophoretic forces. Proteins that differ in their pI values by only 0.02 pH unit have been separated by IEF.

The pH gradient is created with *carrier ampholytes*, a group of amphoteric polyaminocarboxylic acids that have slight differences in pKa value and molecular weights of 300 to 1000. Mixtures of 50 to 100 different compounds are added to the medium and create a “natural pH gradient” when individual ampholytes reach their pI values during electrophoresis. They establish narrow buffered zones, with stable but slightly different pHs, through which the slower-moving proteins migrate and stop at their individual pIs.

The anode is surrounded by a dilute acid solution and the cathode by a dilute alkaline solution. After focusing, the most negatively charged carrier ampholytes and proteins will be found at the anodal end, and the most positively charged near the cathodal end of the electrophoretic matrix. The other carrier ampholytes and proteins focus at intermediate points according to their pI values. Because carrier ampholytes are generally used in relatively high concentrations, a high-voltage power source (up to 2000 V) is necessary (power is in the vicinity of 2 to 50 W, depending on experimental conditions). As a result, the electrophoretic matrix must be cooled.

PAGE-IEF is widely used in analytical work, as it is essentially free of electroendosmosis. However, the polyacrylamide gel must have a large enough pore size so that protein migration will not be impeded by molecular sieving effects. In actual practice, impeded migration of some proteins, such as IgM, cannot be prevented. PAGE-IEF has the advantages that operating conditions are simple, and

that large pore sizes make it unlikely that any proteins will be excluded on the basis of molecular size. IEF has been applied to the separation of alkaline phosphatase isoenzymes and is widely used in neonatal screening programs to test for variant hemoglobins. Off-gel techniques carry out the separation in free solution with sample containing ampholytes loaded into each of a linear series of wells separated by semipermeable membranes and in contact with a pH gradient strip. Electrophoresis separates sample proteins into different wells depending on their pI values. Separated fractions can be further resolved in a second similar focusing step or taken directly to further separation by two-dimensional electrophoresis or liquid chromatography-mass spectrometry. This technique has been useful in the study of the human proteome.

Micellar Electrokinetic Chromatography

MEKC is a hybrid of electrophoresis and chromatography. MEKC, a mode that is separate and distinct from capillary electrokinetic chromatography, is an effective electrophoretic technique, because it can be used for the separation of neutral and charged solutes. The separation of neutral species is accomplished by exploiting micelles formed in the running buffer when the concentration of surfactant exceeds the critical micelle concentration (e.g., 8 to 9 mmol/L for SDS). During electrophoresis, neutral micelles can interact with analytes in a chromatographic manner through hydrophobic interactions in which analytes are micellized based on their degree of hydrophobicity. Under these conditions, partitioning into the micelle is the driving force for separation. With charged micelles (e.g., SDS), analytes can also interact through electrostatic interactions via the charge on the surface of the micelle.

REVIEW QUESTIONS

1. For proteins to migrate on a gel during electrophoresis, the isoelectric point must be exceeded. The isoelectric point of an amino acid or protein is defined as the:
 - a. ability of the amino acid or protein to carry both positive and negative charges.
 - b. pH at which the amino acid or protein has a negative charge.
 - c. pH at which a molecule has no net charge.
 - d. point on an electrophoretic gel at which that specific protein migrates.
2. The term *amphoteric* means:
 - a. the pH at which a protein has no net charge.
 - b. that a protein will have a negative charge at a high pH.
 - c. that a protein has both positive and negative charges because of its side chains.
 - d. the positive electrode.
3. Unequal migration of samples down the gel in an electrophoresis assay is an interference usually caused by:
 - a. dirty electrodes causing uneven application of the electrical field.
 - b. dirty pipette tips or applicators.
 - c. too much sample being applied.
 - d. inappropriate binding of immunoglobulins to other proteins in a sample.
4. In serum protein electrophoresis, the greater the charge of a molecule:
 - a. the slower it will migrate.
 - b. the faster it will migrate.
 - c. the less the migration rate will be affected.
5. Serum protein electrophoresis is what kind of basic technique?
 - a. Immunoassay
 - b. Standardization
 - c. Qualitative technique
 - d. Separation

6. Specimens with very low protein content sometimes require preconcentration before they are loaded onto an electrophoretic gel. An electrophoretic technique that *does not* require this concentration step is:
 - a. disc electrophoresis.
 - b. capillary electrophoresis.
 - c. zone electrophoresis.
 - d. two-dimensional gel electrophoresis.
7. What optical measuring technique allows for the scanning and quantification of electrophoretic fractions separated on a support medium?
 - a. Spectrophotometry
 - b. Chromatography
 - c. Densitometry
 - d. Nephelometry
8. A Southern blot is used to detect fragments of:
 - a. RNA.
 - b. protein.
 - c. agarose.
 - d. DNA.
9. A 1% agarose gel is best suited for separating DNA fragments in which one of the following size ranges:
 - a. 500 bp (0.5 kbp) to 20 kbp
 - b. 50 to 100 kbp
 - c. 100 to 500 kbp
 - d. larger than 500 kbp
10. The component of an electrophoresis system in which separation takes place is the:
 - a. stain.
 - b. support medium.
 - c. densitometer.
 - d. zone.

Chromatography

David S. Hage*

OBJECTIVES

1. Define the following terms:
 - Chromatogram
 - Chromatograph
 - Chromatography
 - Column chromatography
 - Mobile phase
 - Planar chromatography
 - Retention factor
 - Retention time and retention volume
 - Stationary phase
 - Void time and void volume
2. Evaluate a chromatogram and its peaks to determine their separation factor and resolution; list three ways to improve resolution.
3. Define and calculate the following terms for a chromatographic separation: number of theoretical plates and plate height. Explain how the plate height can vary with the linear velocity of the mobile phase.
4. Explain how external or internal calibration can be used for quantitative measurements in chromatography. Define *internal standard* and discuss how this can be used in quantitative measurements by chromatography.
5. Define gas chromatography (GC) and describe three types of GC based on the type of stationary phase that is present. List some stationary phases for each of these methods.
6. Summarize the components of a gas chromatograph and describe the function of each component.
7. Explain the differences between packed columns and capillary columns in GC.
8. Define the following terms and explain how they are used in GC: headspace analysis, isothermal elution, and temperature programming.
9. List and describe five types of detectors that are used in GC, including the advantages and disadvantages of each.
10. Define the terms *liquid chromatography* and *high-performance liquid chromatography*. List several ways in which liquid chromatography differs from GC.
11. Describe the following types of liquid chromatography, including the principles of separation, the types of stationary phases and mobile phases that are used, and some possible clinical applications of each.
 - Adsorption chromatography
 - Affinity chromatography
 - Hydrophilic interaction liquid chromatography
 - Ion-exchange chromatography
 - Ion-pair chromatography
 - Normal-phase chromatography
 - Reversed-phase chromatography
 - Size-exclusion chromatography
12. Summarize the components of a system that are used in high-performance liquid chromatography and describe the function of each component.
13. List and describe five types of detectors that are used in liquid chromatography, including the advantages and disadvantages of each.
14. Explain the principles of planar chromatography. Define the terms *paper chromatography* and *thin-layer chromatography*.
15. Know how to calculate and use the retardation factor to identify compounds in planar chromatography.

KEY WORDS AND DEFINITIONS

Adsorption chromatography A type of liquid chromatography in which chemicals are retained based on their adsorption and desorption at the surface of an underivatized support.

Affinity chromatography (AC) A liquid chromatographic method that makes use of biologically related interactions for the retention and separation of chemicals.

*The author gratefully acknowledges the contributions of Drs. Glen L. Hortin, Bruce A. Goldberger, M. David Ullman, Carl A. Burtis, and Larry D. Bowers to this chapter in previous editions.

Anion-exchange chromatography A type of ion-exchange chromatography that uses positively charged groups as a stationary phase to bind and separate anions.

Bonded phase gas chromatography A type of gas chromatography in which the stationary phase is chemically linked or attached to the support.

Carrier gas A term often used to describe the mobile phase in gas chromatography.

Cation-exchange chromatography A type of ion-exchange chromatography that uses negatively charged groups as a stationary phase to bind and separate cations.

Chiral stationary phase (CSP) A stationary phase that is chiral and that can interact with compounds in a stereospecific manner.

Chromatogram A plot of detector response in chromatography as a function of the time or volume of the mobile phase that is needed to elute an analyte from a column.

Chromatograph The instrument that is used to perform a separation in chromatography.

Chromatography A method in which the components of a mixture are separated based on their differential interactions with two chemical or physical phases: a mobile phase and a stationary phase.

Column chromatography A type of chromatography that uses a column, or a tube, to contain the stationary phase and support.

Gas chromatography (GC) A type of chromatography that uses a gas as the mobile phase.

Gas chromatography/mass spectrometry (GC/MS) The use of a mass spectrometer as a detector for gas chromatography.

Gas-liquid chromatography (GLC) A type of gas chromatography in which the stationary phase is a liquid that is placed as a coating or layer on the support.

Gas-solid chromatography (GSC) A type of gas chromatography in which the same material acts as both the stationary phase and the support; chemicals are retained by their adsorption to the surface of the support.

Headspace analysis A sample introduction technique in which a portion of the vapor phase (or “headspace”) that is above a liquid or solid sample is used in an analysis.

Height equivalent of a theoretical plate (HETP or H) A measure of efficiency in chromatography that is equal to length of a chromatographic system divided by the number of theoretical plates for the system; also known as the *plate height*.

High-performance liquid chromatography (HPLC) A type of liquid chromatography that uses small, efficient supports that produce narrow peaks.

Hydrophilic interaction liquid chromatography (HILIC) A type of partition chromatography that uses a polar stationary phase, and in which chemicals partition between an organic-rich region in the mobile phase and a more polar water-enriched layer that is at or near the surface of a polar support.

Internal standard A compound that is added in a constant amount to standard solutions and samples to help normalize the results for any variations that may occur during pretreatment steps or during injection into a chromatographic system.

Ion-exchange chromatography (IEC) A type of liquid chromatography in which ions are separated by their adsorption onto a support that contains fixed charges at its surface.

Ion-pair chromatography (IPC) A technique that combines columns that are used in reversed-phase chromatography with the ability to separate ionic compounds based on their charges, as achieved by adding an ion-pairing agent to the mobile phase.

Isocratic elution Use of a constant mobile phase composition throughout a separation.

Isothermal elution A chromatographic method that uses a constant temperature for elution.

Liquid chromatography (LC) A type of chromatography that uses a liquid as the mobile phase.

Liquid chromatography–electrochemical detection (LC-EC) The combination of an electrochemical detector with liquid chromatography.

Liquid chromatography–mass spectrometry (LC-MS) A technique that combines liquid chromatography with mass spectrometry.

Mobile phase The phase that travels through a chromatographic system and carries sample components with it.

Normal-phase chromatography A type of partition chromatography that uses a polar stationary phase; also known as “normal-phase liquid chromatography,” or NPLC.

Number of theoretical plates (N) A measure of efficiency and band-broadening that is given for a Gaussian-shaped peak by using either $N = 16 (t_R/W_b)^2$ or $N = 5.545 (t_R/W_h)^2$, where t_R is the retention time for the peak, and W_b or W_h are baseline width or half-height width for the peak. The number of theoretical plates is also known as the *plate number*.

Partition chromatography A liquid chromatographic method in which solutes are separated based on their partitioning between the liquid mobile phase and a stationary phase that is coated or bonded onto a solid support.

Planar chromatography A type of chromatography in which the stationary phase is coated or placed onto a flat surface, or plane.

Resolution (R_s) A measure of the separation of two adjacent peaks in chromatography; the resolution equals the difference in retention time for the components in the two peaks divided by the average of the baseline widths for these peaks.

Retardation factor (R_f) In planar chromatography, the distance traveled by a chemical from its point of application divided by the distance traveled by the mobile phase in the same amount of time.

Retention factor (k) A measure of retention in chromatography, which is equal to the difference in the retention time and void time divided by the void time, or the difference in the retention volume and void volume divided by the void volume; also called the *capacity factor*.

Retention time (t_R) The average time that is required for a particular chemical to pass through a chromatographic column.

Retention volume (V_R) The average volume of mobile phase that is required for a particular chemical to pass through a chromatographic column.

Reversed-phase chromatography A type of partition chromatography that uses a nonpolar stationary phase; also known as *reversed-phase liquid chromatography* (RPLC).

Separation factor (α) A measure of the degree of separation in chromatography that is equal to the ratio of the retention factors for two neighboring peaks, where the larger retention factor appears in the numerator; also known as the *selectivity factor*.

Size-exclusion chromatography (SEC) A liquid chromatographic technique that separates analytes based on size through the use of a porous support that has an inert surface with little or no interactions with the sample components.

Solvent programming Use of a mobile phase composition that varies during a separation.

Stationary phase The phase in chromatography that is held within the system by a support and used to interact with and separate a sample's components as these components pass through the system.

Temperature programming A chromatographic method in which the temperature is changed over time.

Ultra-high-performance liquid chromatography (UPLC or UHPLC) A liquid chromatographic method that uses smaller diameter supports and pressures up to 15,000 psi.

van Deemter equation A relationship that shows how the overall value of plate height (H) for a chromatographic system is affected by the linear velocity of the mobile phase (u), where $H = A + B/u + C u$ and the terms A , B , and C are constants that represent the contributions of several types of band-broadening processes.

Void time (t_M) The elution time for a compound that is not retained in a chromatographic system.

Void volume (V_M) The volume of mobile phase that is needed to elute a compound that is not retained in a chromatographic system.

BASIC PRINCIPLES OF CHROMATOGRAPHY

General Terms and Components of Chromatography

Chromatography is a method in which the components of a mixture are separated based on their differential interactions with two chemical or physical phases: a **mobile phase** and a **stationary phase** (Fig. 12.1). The mobile phase travels through the system and carries sample components with it once the sample has been applied or injected. The stationary phase is held within the system by a support. As a sample's components pass through this system, the components that have the strongest interactions with the stationary phase will be retained more and move through the system more slowly than components that have weaker interactions. This leads to a difference in the rate of travel for these components and their separation.

The type of chromatographic system that is shown in Fig. 12.1 is known as **column chromatography** because it uses a column (or a tube) to contain the stationary phase and support. The stationary phase may be the surface of the support, a coating on this support, or a chemical layer that is bonded to the support. In column chromatography, the support may be the interior wall of the column, or it may be a material that is placed or "packed" into the column. It is also possible to use a support and stationary phase that are present on a plane, or open surface. This second format is known as **planar chromatography**.

Besides being classified based on whether they use a column or plane, chromatographic methods can be classified based on the mobile phase. For instance, a chromatographic

method that uses a mobile phase that is a gas is called **gas chromatography** (GC), while a chromatographic method that uses a liquid mobile phase is known as liquid chromatography (LC). It is also possible to divide chromatographic methods according to the type of stationary phase that is present or the way in which this stationary phase is interacting with sample components. Examples include the GC methods of **gas-solid chromatography** (GSC) or **gas-liquid chromatography** (GLC), and the LC methods of **adsorption chromatography** or **partition chromatography**.

The instrument that is used in chromatography is known as a **chromatograph**. This instrument can provide a response that is related to the amount of a compound that is exiting (or eluting) from a column as a function of the elution time or the volume of mobile phase that has passed through the system. The resulting plot of the response versus time or volume is known as a **chromatogram**, as illustrated in Figs. 12.1 and 12.2.

The average time or volume that is required for a chemical to pass through the column is known as that chemical's **retention time** (t_R) or **retention volume** (V_R). The elution time or volume for a compound that has no interaction with the stationary phase and is not retained is known as the **void time** (t_M) or **void volume** (V_M). In order for two chemicals to be separated by chromatography, it is necessary for these chemicals to have different values for t_R and V_R . Retention times or retention volumes can be used to help identify the eluting compounds, while the area or height of the compound's peak can be used to measure the amount of the compound that is present.

Fig. 12.1 The general components of a chromatographic system, as illustrated here by using a column to separate two chemicals, A and B.

Column: C18, 3 μm , $0.46 \times 10 \text{ cm}$
 Eluent: Isocratic, 0.025 M phosphate
 Buffer: pH 3.0 in 25% acetonitrile
 Flow rate: 2 mL/min
 Detection: 215 nm, 0.1 AUFS

Compounds: 1. Doxepin
 2. Desipramine
 3. Imipramine
 4. Nortriptyline
 5. Amitriptyline

Fig. 12.2 Chromatogram from a separation of tricyclic antidepressants based on reversed-phase chromatography and high-performance liquid chromatography. Detection was based on the use of an absorbance detector that monitored the column eluent at 215 nm. (Note: the signal is displayed at 0.1 AUFS [absorbance units-full scale].) (Courtesy Grace Vydac Separations Group Inc., Hesperia, CA.)

The width of each peak reflects the separating “performance” or “efficiency” of the chromatographic system. The width of a peak in a chromatogram is often represented by its baseline width (W_b) or its half-height width (W_h) (Fig. 12.3). As the widths of the peaks in a chromatogram decrease, and the peaks become sharper, it becomes easier for the chromatographic system to separate two neighboring peaks and to separate multiple peaks in a given amount of time. Sharper peaks are also easier to measure than broader peaks and tend to produce better limits of detection.

Retention and Selectivity

For two chemicals to be separated by chromatography, these chemicals need to have some differences in how they are interacting with the stationary phase versus the mobile phase. These different interactions lead to differences in retention between the two chemicals. Besides using the retention time or retention volume, another way of representing retention in chromatography and identifying compounds is by using the **retention factor (k)**, which is also sometimes called k' or the “capacity factor.” This value can be calculated from experimental data by using either of the following equivalent relationships:

$$k = (t_R - t_M) / t_M$$

$$\text{or } k = (V_R - V_M) / V_M$$

The retention factor is a unitless number, where a value of zero indicates that no interaction is occurring between a chemical and the stationary phase. As a chemical undergoes greater interactions with the stationary phase, this will result in longer retention times and an increased value of k . The value of k is directly related to the strength of the interactions that are occurring between a chemical and the stationary phase or mobile phase, as well as the relative amount of stationary phase versus mobile phase that is present in the column.

Fig. 12.3 An example of a general chromatogram that may be obtained when using a column. In this example, compound B is eluted later than compound A. R_s , Resolution; t_M , void time; $t_{R,A}$ and $t_{R,B}$, retention times for solutes A and B; $W_{b,A}$ and $W_{b,B}$, baseline peak widths for compounds A and B.

Any separation in chromatography requires that there be some difference in retention for the chemicals of interest. One way of describing this difference is by using the **separation factor** or “selectivity factor” (α). The separation factor for two compounds (A and B) is equal to the ratio of their retention factors (k_A and k_B),

$$\alpha = k_B/k_A$$

where the retention factor for the later eluting component (k_B) is given in the numerator. If two chemicals, A and B, have the same retention in a chromatographic system, the value of α will equal one. If A and B have different retention, the value of α will be greater than 1 and will increase as the degree of separation increases.

Band-Broadening and Efficiency

The peaks for two sequentially eluting chemicals must also be sufficiently narrow to allow a difference in retention to be observed. The peaks observed from the injection of even a small sample will experience some increase in width, or band-broadening, as the chemical travels through a chromatographic system. This broadening is produced by various processes that are related to the rate of movement of the applied chemicals as they pass around or within the support and within or between the mobile phase and stationary phase.

The efficiency and degree of band-broadening in a chromatographic system are reflected by the width of a chemical's peak. This width can be described by using the baseline width (W_b) or the half-height width (W_h) of the peak. These values, in turn, can be used to find another measure of chromatographic efficiency that is known as the **number of theoretical plates** or *plate number* (N). The value of N can be found for a Gaussian-shaped peak by using either of the following equivalent formulas:

$$N = 16(t_R/W_b)^2 \quad \text{or} \quad N = 5.545(t_R/W_h)^2$$

where t_R is the retention time for the peak, and the widths W_b or W_h are in the same units of time as t_R . The value of N can be thought of as representing the effective number of times

that a chemical distributes between the mobile phase and stationary phase as the chemical passes through the chromatographic system. A larger value for N represents many such steps, which makes it easier to separate two chemicals that have only small differences in their retention.

Another way to describe the efficiency of a chromatographic system is to use the **height equivalent of a theoretical plate** or “plate height” (HETP or H). The value of H is found by dividing the length (L) of the chromatographic system by the number of theoretical plates for the system (N):

$$H = L/N$$

The value of H represents the length of the column or chromatographic system that makes up one theoretical plate, or one distribution step, for a chemical between the mobile phase and stationary phase. A chromatographic system with high efficiency will have a small value for H .

A valuable feature of using H to describe efficiency is that this term can be related directly to the parameters and processes that affect band-broadening. An example of this is the **van Deemter equation**, showing how H is affected by the linear velocity of the mobile phase (u), which is directly related to the flow rate (F) through the relationship $u = (F \cdot L)/V_M$.

$$H = A + B/u + Cu$$

The terms A, B, and C in this equation are constants that represent the contributions of several types of band-broadening processes. The A term represents band-broadening processes that are independent of the linear velocity, the B term represents processes that produce more band-broadening at low linear velocities, and the C term represents processes that lead to an increase in H as the linear velocity is increased. The van Deemter equation predicts that the combined effect of all these processes will be an optimum range of flow rates and linear velocities over which the lowest plate heights, and best efficiencies, will be obtained.

Several factors affect chromatographic efficiency. For instance, efficiency can be improved by using longer columns, which increases the value of N but does not alter H . It is also possible to change the flow rate to its optimum value, use a smaller diameter or more efficient supports; or use a relatively narrow diameter capillary instead of a packed bed column. All of these latter factors help lower the value of H , which in turn increases the value of N for a given length of column or chromatographic system.

Resolution

The overall extent to which two peaks are separated in chromatography can be described by using the **resolution** (R_s), as illustrated in Fig. 12.3. The resolution between two neighboring peaks can be found by using the following formula:

$$R_s = \frac{(t_{R,B} - t_{R,A})}{(W_{b,B} + W_{b,A})/2}$$

In this equation, $t_{R,A}$ and $t_{R,B}$ are the average retention times for compounds A and B (where B elutes after A), while $W_{b,A}$ and $W_{b,B}$ are the baseline widths for the peaks

Fig. 12.4 Degree of separation obtained for two chromatographic peaks that are present in a 1:1 area ratio as the resolution between these peaks (R_s) is varied.

of these compounds (in time units, in this case). An equivalent equation can be written in terms of retention volumes and baseline widths in volume units. Either approach will give a unitless value for R_s that represents the average number of baseline widths that separate the centers of the two peaks.

Fig. 12.4 shows how the separation of two neighboring peaks increases as the value of R_s increases for these peaks. An R_s value of zero is obtained when there is no separation between the peaks and they have the exact same retention. An R_s value of 1.5 or greater is often said to represent a complete separation between two equally sized peaks, or “baseline resolution.” However, for many separations, resolution values between 1.0 or 1.25 and 1.5 may be adequate, especially if the peaks are about the same size and are to be measured by using their peak heights rather than their peak areas.

There are several approaches that can be used to improve the resolution between two peaks in chromatography (**Fig. 12.5**). These approaches are indicated by the following expression, which is sometimes known as the *resolution equation* of chromatography:

$$R_s = \left[(N^{1/2})/4 \right] \cdot [(\alpha - 1)/\alpha] \cdot [k/(1 + k)]$$

In this equation, k is the retention factor for the second of two neighboring peaks, α is the separation factor for the peaks, and N is the number of theoretical plates for the chromatographic system. This relationship indicates that peak resolution can be increased in three ways: (1) by increasing the efficiency of the system, as represented by N ; (2) by increasing the overall degree of retention, as represented by k ; or (3) by increasing the selectivity of the column for one compound versus another, as represented by α .

Fig. 12.5 Effects of selectivity and efficiency on the resolution of peaks in chromatography. These three situations represent cases where there is (A) poor or moderate resolution between two neighboring peaks, (B) good resolution between the peaks as a result of high column efficiency, or (C) good resolution between the peaks as a result of good column selectivity.

POINTS TO REMEMBER

General Ways to Improve Peak Resolution in Chromatography

- Increase the efficiency of the system.
- Increase the overall degree of peak retention.
- Increase the selectivity of the column for the peak of one compound versus another.

Analyte Identification and Quantification

Chromatography is often used to identify analytes and/or to measure their concentrations. For example, the retention time, retention volume, and retention factor all reflect how an analyte is interacting within a particular chromatographic system. These retention values can be compared with those for a known sample of the same compound to confirm its identity. An alternative approach for identification is to use a detection method that provides structural information on the analyte, such as mass spectrometry (see [Chapter 13](#)).

The peak area or peak height can be used to produce quantitative information on an analyte. Peak areas tend to provide a more precise means for measuring an analyte, while peak heights are easier to use if there is not complete resolution between the analyte and its neighboring peaks. Both external

Fig. 12.6 Use of external calibration and standards to quantify an analyte based on its peak height or area in a chromatogram for an injected sample.

and internal calibration techniques can be used for such measurements. In external calibration, standard solutions containing known quantities of the analytes are processed and separated in the same manner as samples that contain one or more of these analytes (Fig. 12.6). A calibration curve is then constructed by plotting the peak height or peak area (or the spot density, in the case of planar methods) versus the concentration or mass of analyte that was applied in the standard solutions. This curve can then be used with the peak area or peak height that is determined for the same analyte in the samples to find the concentration or the amount of the analyte that was present.

In the method of internal calibration, standard solutions of the analyte are again prepared; however, a constant amount of a different compound known as the **internal standard** is also added to each standard solution and sample (Fig. 12.7). The internal standard should be a chemical that was not originally present in either the sample or the standard, that is similar in its chemical and physical properties to the analyte, and that can be measured independently from the analyte. This internal standard is typically added to the samples and standards before they are processed by any pretreatment steps. The addition of this agent can help normalize the results for any variations that may occur during the pretreatment steps or during injection onto the chromatographic system. This normalization is made by constructing a calibration curve in which the y -axis is based on the ratio of the peak height or peak area for the analyte in a given standard or sample divided by the peak height or peak area for the internal standard in the same

Fig. 12.7 Use of internal calibration and samples or standards containing an internal standard (I.S.) to quantify an analyte based on its peak height or area in a chromatogram for an injected sample.

standard or sample. This ratio is plotted versus the concentration or amount of analyte that was in each standard. This calibration plot can then be used to find the concentration or the amount of the analyte in each sample.

GAS CHROMATOGRAPHY

GC is a type of chromatography in which a gas is used as the mobile phase. This method can be used to separate and analyze compounds that either are naturally volatile or can be converted into a volatile form, such as through derivatization. The mobile phase is typically an inert gas such as nitrogen, helium, or argon, or a low mass gas such as hydrogen. Due to the low densities of gases, the compounds that are injected onto a GC column do not have any appreciable interactions with the mobile phase but are simply carried by this gas through the column. As a result, the term **carrier gas** is commonly used to refer to the mobile phase in GC. Separations in GC are instead based on differences in the vapor pressures of the injected compounds and in the interactions of these compounds with the stationary phase.

Types of Gas Chromatography

Gas-Solid Chromatography

There are several ways of classifying GC methods based on the type of stationary phase that is present. GSC is a type of GC in which the same material acts as both the stationary phase and the support. In this method, chemicals are retained by their adsorption to the surface of the support. This support is often an inorganic material like silica or alumina. Other

TABLE 12.1 Stationary Phases Commonly Used in Gas-Liquid Chromatography and as Bonded Phases in Gas Chromatography

Composition	Polarity	Commercial Examples	Typical Applications
100% Methylpolysiloxane	Nonpolar	OV-1, SE-30	Drugs, amino acid derivatives
5% Phenyl–95% methylpolysiloxane	Nonpolar	OV-23, SE-54	Drugs
50% Phenyl–50% methylpolysiloxane	Intermediate polarity	OV-17	Drugs, steroids, glycols
50% Cyanopropylmethyl–50% phenylmethylpolysiloxane	Intermediate polarity	OV-225	Fatty acid methyl esters, carbohydrate derivatives
Polyethylene glycol	Polar	Carbowax 20M	Acids, alcohols, glycols, ketones

**Fig. 12.8** General structure of a polysiloxane. The side groups are represented by R_1 through R_4 , while n and m represent the relative lengths (or amounts) of each type of segment in the overall polymer.

supports that can be used are molecular sieves, which are porous materials that are made from a mixture of silica and alumina, or organic polymers like porous polystyrene. The retention of an analyte on a GSC support will be affected by factors such as the surface area of the support, the size of the pores in this support, and the types of functional groups that are present on the support.

Gas-Liquid Chromatography and Bonded Phases

In GLC the stationary phase is a liquid that is placed as a coating or layer on the support. This is the most common type of GC for chemical analysis. Various types of liquids can be used for this purpose (Table 12.1). Many GLC stationary phases are based on a polysiloxane (Fig. 12.8). The side chains in a polysiloxane can have structures that range from nonpolar methyl groups to polar cyanopropyl groups, and may be present in various ratios or as mixtures. The types of chemicals that will be retained by this type of stationary phase will be determined by the amounts and types of side chains that are present.

One issue in using a liquid as a stationary phase in GC is that some of this liquid will eventually leave the column over time in a process known as “column bleed.” This process results in a change in the ability of the GC system to retain chemicals and may cause the signal of a detector to have a high background or to be noisy as the stationary phase leaves the column. Column bleed can be minimized by using a bonded phase (i.e., a stationary phase that is chemically linked or attached to the support) instead of a liquid as the stationary phase in the GC column. The resulting method is sometimes known as **bonded phase gas chromatography**.

Gas Chromatography Instrumentation

Carrier Gas Sources and Flow Control

The typical components of a gas chromatograph are shown in Fig. 12.9. The carrier gas is usually supplied by a standard gas cylinder. However, a gas generator can also be connected to the GC system to isolate nitrogen from air or to produce hydrogen gas through the electrolysis of water. Good flow control is needed to maintain good column efficiency and provide reproducible retention times. The flow can be controlled by using a simple pressure regulator or a more sophisticated electronic device.

The choice of the carrier gas will depend on the expense, purity, and chemical or physical properties of the gas. Carrier gas impurities such as water, oxygen, and hydrocarbons can harm or alter the column and influence the performance of some detectors. Molecular sieves and traps are often used to remove water, hydrocarbons, oxygen, and particulate matter that may be present in the carrier gas.

Many GC detectors work best with certain types of carrier gases. For instance, nitrogen is often used as the carrier gas when working with a flame ionization detector (FID), electron capture detector (ECD), or thermal conductivity detector (TCD), as described in more detail later. Helium is often used with a FID or TCD, and nitrogen/argon-methane mixtures are used with an ECD.

Injection Systems and Sample Derivatization

Most clinical GC methods make use of liquid-phase samples, from which the sample components are first extracted into a nonaqueous liquid or adsorbed onto a microextraction

fiber. This liquid or microextraction fiber is then placed into the GC system by using a precise and rapid online injector (e.g., an autosampler or automated injection system). With packed columns, a glass microsyringe is used to inject a sample through a septum and into a heated injection port. *Volatile* chemicals in the sample and the solvent are quickly vaporized in this heated port and swept into the column by the carrier gas. Common problems during injection include septum leaks and the adsorption of sample components onto the septum. In addition, because the injection port is heated, thermal decomposition may occur and result in spurious peaks in the chromatogram for some compounds.

Because of the low sample capacities and slow carrier gas flow rates that are used with capillary columns, split and splitless injection techniques are used to introduce samples into such columns. For a split injection, only a small portion of the vaporized sample enters the column, with the remainder being passed through a side vent. In splitless injection, most of the sample enters the column. The split flow injection mode is used for samples that contain relatively high concentrations of the analytes, while the splitless mode is used for samples that contain lower concentrations. Temperature-programmable injection ports are also available and may be used in either injection mode to reduce the time that thermally unstable compounds are exposed to high temperatures in the port.

Headspace analysis is a sample introduction technique that can be used with aqueous solutions or samples that contain some nonvolatile components. In this method, a portion of the vapor phase (or “headspace”) that is above a liquid or solid sample is used for the analysis. This vapor phase contains some of the more volatile sample components and can be directly injected onto a GC system. Headspace analysis can be carried out by using either a static method or a dynamic method. In the static method, the sample is placed in an enclosed container and allowed to reach equilibrium for the distribution of its components between the sample and the vapor phase above the sample. A portion of the vapor phase is then injected onto the GC system. In the dynamic method, an inert gas is passed through the sample and used to sweep away the volatile components. These components are then captured by a solid adsorbent or a cold trap and later injected onto the GC system.

Although a fairly large number of low-mass chemicals can be injected directly onto a GC system, many more are not sufficiently volatile or thermally stable for direct injection. A way to make a chemical more volatile and thermally stable is to alter its structure through derivatization. This usually involves replacing one or more polar groups on the analyte with less polar groups. A common example is the replacement of an active hydrogen on an alcohol, phenol, amine, or carboxylic acid group with a trimethylsilyl (TMS) group, producing a TMS-derivative. Other examples include the use of alkylation (e.g., the formation of a methyl ester through the esterification of a carboxylic acid) or acylation (e.g., the production of an acetate derivative from an alcohol or amine). Some derivatization reactions can also be used to change the response of an analyte to certain detectors, such as an ECD through the addition of halogen atoms to a compound's structure.

Columns and Supports

Both packed columns and capillary columns are used in GC. Packed GC columns are filled with support particles that contain the stationary phase and have typical inner diameters of 1 to 4 mm and lengths of 1 to 2 m. Packed GC columns are useful when it is necessary to apply a relatively large amount of a sample onto the GC system. However, packed columns also tend to have lower efficiencies than capillary columns, so they are mainly used in applications for which a relatively small number of compounds are to be separated.

Capillary columns, or open-tubular columns, consist of a column that has the stationary phase attached to or coated on its interior surface. Capillary columns have typical inner diameters of 0.1 to 0.75 mm and lengths that often range from 10 to 150 m. Capillary GC columns are usually made from fused silica capillaries that have a polyimide or aluminum coating on the outside to give the capillary sufficient strength and flexibility for use in a GC system. Although capillary columns have lower sample capacities than packed columns, they provide better peak resolution and higher efficiencies. These properties make capillary columns the most common type of support that is used in GC for analytical applications.

Temperature Control

All GC systems require careful control of temperature with a column oven to obtain optimal performance and reliable results. The column may be maintained at a constant temperature (i.e., **isothermal elution**), or the temperature may be varied over time (i.e., **temperature programming**). Temperature programming is used for most clinical applications. In temperature programming, the sample components with the lowest boiling points and weakest interactions with the GC column will elute first, followed by chemicals that have higher boiling points and/or stronger interactions with the column. Temperature programming usually provides sharper and more distinct peaks in less time than can be obtained with isothermal elution. The main advantage of isothermal elution is that it can be faster for samples that do not contain a wide range of chemicals with different volatilities.

The thermal stabilities of the stationary phase and column are important to consider during the development of a GC method. Because each stationary phase has a specific temperature range over which it is stable, it is necessary to keep the column temperature within this usable range. Before any GC column is used for a routine analysis, it must be “thermally conditioned” by heating the column at various temperatures and for given lengths of time. This process helps remove volatile contaminants that may be initially present in the column or that have accumulated and can lead to unstable baselines. Preconditioned capillary columns are also available to minimize these problems.

Gas Chromatography Detectors

Flame ionization detector. A variety of detectors can be used in GC systems (Table 12.2). An FID is commonly used with GC in clinical laboratories for the analysis of ethanol and other volatiles in blood or aqueous samples (Fig. 12.10). During the operation of an FID, the carrier gas that is leaving the column is mixed with hydrogen, and the eluting

TABLE 12.2 Examples of Detectors Used in Gas Chromatography

Type of Detector	Principle of Operation	Selectivity	Approximate Limit of Detection
Flame ionization detector (FID)	Production of gas phase ions from combustion of organic compounds	General—Organic compounds	10^{-12} g Carbon
Nitrogen-phosphorus detector (NPD)	Heated alkali bead selectively ionizes N- or P-containing compounds	Nitrogen- or phosphorus-containing compounds	10^{-14} – 10^{-13} g Nitrogen or phosphorus
Electron capture detector (ECD)	Capture of electrons by chemicals with electronegative groups	Chemicals with electronegative groups	10^{-15} – 10^{-13} g
Mass spectrometry (MS)	Production of gas phase ions, followed by separation/analysis of these ions based on their mass-to-charge ratios	Universal—full-scan mode Selective—selected ion monitoring mode (SIM)	10^{-10} – 10^{-9} g Full-scan mode 10^{-12} – 10^{-11} g SIM mode
Thermal conductivity detector (TCD)	Measurement of change in thermal conductivity of carrier gas as compounds elute from the column	Universal	10^{-9} g
Flame photometric detector (FPD)	P- and S-containing compounds emit light when burned in a flame; emitted light is detected	Phosphorus and sulfur-containing compounds	10^{-12} g Phosphorus 10^{-11} g Sulfur

Portions of this table are based on data from Hage, D. S., & Carr, J. D. (2011). *Analytical chemistry and quantitative analysis*. New York: Pearson, and references cited therein.

Fig. 12.10 Chromatograms obtained during the analysis of volatile organic compounds when using headspace analysis and gas chromatography with a flame ionization detector (FID). (Courtesy Restek Corporation, Bellefonte, PA.)

compounds are burned by a flame that is surrounded by air and an oxygen-rich environment. This process produces gas-phase ions from organic compounds, with these ions being detected and measured by an electrode that is positioned above the flame.

The advantages of an FID include its simplicity, reliability, and ease of operation. Another advantage of an FID is that this detector gives little or no signal for common carrier gases (e.g., He, Ar, or N₂) or typical contaminants in such gases (e.g., O₂ and H₂O). An FID is easy to use with temperature programming and is a good general detector for the routine clinical analysis of organic compounds. One disadvantage of

the FID is its destructive nature, so it cannot be connected directly to other GC detectors.

Nitrogen-phosphorus detector. The nitrogen-phosphorus detector (NPD) is similar to an FID but instead creates gas-phase ions by using an electrically heated alkali bead that is generally made of rubidium. This heated bead is placed directly above the point where a mixture of the carrier gas and hydrogen enter the detector. Ions are generated at or above the surface of the heated alkali bead, which supplies electrons to electronegative compounds and leads to the formation of negatively charged ions, which are then measured at an electrode.

Nitrogen- or phosphorus-containing compounds are especially good at creating ions in an NPD. This feature makes the NPD useful for monitoring low concentrations of analytes that have nitrogen or phosphorus in their structures, such as many organic bases and acids. This type of detector does not respond to common GC carrier gases or their impurities. However, it is necessary to regularly change the alkali bead in this detector because this bead will degrade over time.

Electron capture detector. The ECD is a selective GC detector based on the capture of secondary electrons by electronegative compounds that are eluting from the column. High-energy electrons, or beta particles, are provided in an ECD by a radioactive source such as ^{63}Ni or ^3H . These beta particles collide with the carrier gas and lead to the release of a large number of secondary electrons. When only the carrier gas is passing through this detector, a consistent supply of the secondary electrons is created, which is collected at an electrode and measured. When a chemical with electronegative groups elutes from the column, some of these secondary electrons are captured and fewer reach the electrode, producing a change in the signal.

An ECD can provide both selective and sensitive detection for chemicals that contain electronegative groups. This includes chemicals that contain halogen atoms (I, Br, Cl, and F) or nitro groups ($-\text{NO}_2$). It also includes chemicals that are polynuclear aromatic hydrocarbons, anhydrides, or conjugated carbonyl compounds, among others. Derivatization with reagents containing chlorinated or fluorinated groups can be used with some chemicals to allow them to be monitored with an ECD. Large carrier gases such as argon and nitrogen are usually employed with an ECD because it is easy for them to collide with beta particles and to produce secondary electrons. Some methane is also usually combined with these carrier gases to produce a stable detector response. Because an ECD uses a radioactive source, this source needs to be replaced on a regular basis by a certified technician.

Mass spectrometry. Mass spectrometers are also used as detectors for GC. This combination is known as **gas chromatography/mass spectrometry (GC/MS)**. GC/MS is a powerful method for identifying and quantifying analytes. Ionization methods that are often used in GC/MS include electron impact ionization (EI) and chemical ionization (CI). Mass analyzers that are commonly used in GC/MS are quadrupole mass analyzers and ion traps (see [Chapter 13](#)).

In the “full-scan mode” of GC/MS, information is acquired on a wide range of ions. This mode is used when the goal is to detect many compounds in a single run or to provide data that can be used to identify an unknown compound from its mass spectrum. GC/MS can also examine specific analytes by using selected ion monitoring (SIM) to monitor only a few ions that are representative of the analytes of interest. SIM is used when selective detection and low detection limits are desired.

Other gas chromatography detectors. There are a variety of other detectors that can also be part of a GC system. A TCD is a general detector that can monitor both inorganic and organic compounds based on their ability to change how the carrier

gas/analyte mixture will conduct heat away from a hot wire. The carrier gas used with a TCD is often helium or hydrogen, which have large differences in their ability to conduct heat when compared with most organic or inorganic compounds. The primary advantage of a TCD is its ability to detect many types of chemicals. This detector is nondestructive and can easily be combined with a second detector. However, a TCD can also respond to contaminants in the carrier gas and give a change in the background response during temperature programming. In addition, the TCD tends to have much higher detection limits than other common GC detectors.

Another group of GC detectors make use of the interactions of chemicals with light. One example is a flame photometric detector (FPD). An FPD is a selective detector for phosphorus- or sulfur-containing compounds. Like an FID, an FPD passes the eluting chemicals into a flame, but the FPD then measures the release of light from excited-state phosphorus- or sulfur-containing species.

Data Acquisition and System Control

Computers are used to control and automate GC systems, as well as to collect and process data. The computer can regulate parameters such as the (1) carrier gas composition and flow rate; (2) column back pressure; (3) temperature; (4) sample injection process; (5) detector selection and operation; and (6) timing steps during system operation. In terms of data acquisition, the computer can monitor and store the signals that are generated by the GC system's detectors. The computer system can also be used to search databases to aid in the identification of analytes based on their retention times or their response at the detector.

LIQUID CHROMATOGRAPHY

Liquid chromatography (LC) is a type of chromatography in which the mobile phase is a liquid. Separations in LC are based on the distribution of chemicals between a liquid mobile phase and a stationary phase. LC is the dominant type of chromatography that is currently used for chemical analysis in clinical or biomedical laboratories. A key advantage of this method over GC is the ability of LC to work directly with liquid samples, as are often encountered with clinical or biological specimens.

The supports originally used in LC columns were based on large and irregularly shaped particulate supports like those used in packed columns for GC. These supports were useful in preparative work but were not suitable for many analytical applications because they tended to result in broad peaks and separations with low resolution. Work in the 1960s resulted in smaller, more mechanically stable and more efficient supports for LC, along with the instrumentation that could be used with such materials. This resulted in a method that is now known as **high-performance liquid chromatography (HPLC)**. The use of these more efficient supports made it possible to obtain narrower peaks, better separations, and lower limits of detection than traditional LC. These reasons, along with the ability of HPLC to be used as an automated method, have made this technique the method of choice for most routine chemical separations and analysis methods.

Fig. 12.11 Main types of liquid chromatography based on their separation mechanisms.

Because the pressure drop across a packed bed column increases with a decrease in the support particle's diameter, relatively high pressures can be required to pump liquids through HPLC columns. As a result, this technique has also been referred to as *high-pressure liquid chromatography*. Most modern HPLC systems can work at pressures up to 5000 to 6000 psi. Specialized systems that use even smaller diameter supports and that can operate at pressures up to 15,000 psi have recently been developed resulting in the technique called **ultra-high-performance liquid chromatography (UPLC or UHPLC)**.

One important difference between LC and GC is that the retention of chemicals in LC can depend on the interactions of these chemicals with both the mobile phase and stationary phase. This means the composition of the mobile phase is important to consider when adjusting the retention of a chemical in LC. The term *strong mobile phase* is used to describe a mobile phase that leads to weak retention for an analyte on a given type of stationary phase. The weakest retention for a chemical will occur when this substance favors staying in the mobile phase instead of the stationary phase. The term *weak mobile phase* refers to the opposite situation, in which a chemical favors the stationary phase versus the mobile phase and has its highest retention within a given column.

POINTS TO REMEMBER

Mobile Phase Strength in Liquid Chromatography

The mobile phase is important in liquid chromatography for determining chemical retention.

A "strong mobile phase" is a mobile phase that leads to weak retention for an analyte on a given type of stationary phase and column.

A "weak mobile phase" is a mobile phase in which a chemical favors the stationary phase and has a high retention on a given column.

Types of Liquid Chromatography

Adsorption Chromatography

Liquid chromatographic methods are classified according to the mechanisms by which they separate chemicals (Fig. 12.11). **Adsorption chromatography** is a type of LC in which chemicals are retained based on their adsorption and desorption at the surface of a support that is not derivatized (see Fig. 12.11). This method is sometimes referred to as *liquid-solid chromatography* (LSC). Retention in this method is based on the competition of the analyte with the mobile phase as both bind to the support. The degree of a chemical's retention in adsorption chromatography will depend on (1) the binding strength of this chemical to the support, (2) the surface area of the support, (3) the amount of mobile phase that is displaced from the support by the chemical, and (4) the binding strength of the mobile phase to the support.

Three types of adsorbents are generally used in adsorption chromatography: (1) polar acidic supports, (2) polar basic supports, and (3) nonpolar supports. The most common polar and acidic support is silica, which can adsorb polar compounds and works particularly well for basic substances. Alumina is a polar and basic adsorbent that also retains polar compounds, and especially polar acidic substances. Florisil is a polar and basic support that can be used in place of alumina. Nonpolar supports include charcoal and polystyrene.

Partition Chromatography

Partition chromatography is an LC method in which solutes are separated based on their partitioning between the liquid mobile phase and a stationary phase that is coated or bonded onto a solid support (see Fig. 12.11). The support in most types of partition chromatography is silica. This method originally involved coating a liquid stationary phase onto such a support. However, most current columns in partition

chromatography employ bonded stationary phases, which are more stable than coated stationary phases and provide better column efficiencies.

There are two main types of partition chromatography: normal-phase chromatography and reversed-phase chromatography. **Normal-phase chromatography** uses a polar stationary phase and is also known as *normal-phase liquid chromatography* (NPLC). The stationary phase in this method typically contains groups that can form hydrogen bonds or undergo dipole-related interactions. Examples of these bonded stationary phases are those that contain aminopropyl groups, cyano groups, and diol groups. Because this type of chromatography uses a polar stationary phase, it will have its highest retention for polar compounds. A weak mobile phase in this method will be a nonpolar liquid. A strong mobile phase is a more polar liquid, such as methanol or water.

Normal-phase chromatography can be used in many of the same applications as adsorption chromatography based on silica or alumina supports. These applications usually involve the separation or analysis of chemicals that are present in organic solvents and of substances that contain one or more polar functional groups. Examples of chemicals for which normal-phase chromatography has been used include steroids and sugars.

The second type of partition chromatography is **reversed-phase chromatography**, which is also known as *reversed-phase liquid chromatography* (RPLC). Reversed-phase chromatography uses a nonpolar stationary phase and is the most popular type of LC. One reason for this is that the weak mobile phase in reversed-phase chromatography is a polar solvent, such as water. This property makes this type of LC convenient for the analysis and separation of chemicals in aqueous-based systems, such as serum, urine, and blood. A strong mobile phase in this method is a liquid that is less polar than water, such as acetonitrile or methanol. Due to the presence of a nonpolar stationary phase, nonpolar compounds will have the highest retention in reversed-phase chromatography.

There are many applications for reversed-phase chromatography in clinical chemistry and biomedical research (see the example in Fig. 12.2). Examples of chemicals that have been separated or analyzed by this method include drugs, drug metabolites, amino acids, peptides, proteins, carbohydrates, lipids, and bile acids. It is important to consider both the type of analyte and support that are being used in these separations. For instance, large chemicals such as peptides or proteins will require reversed-phase supports with larger pore sizes than the supports that are used for separating small molecules.

The most common stationary phases used in reversed-phase chromatography are based on octadecyl (C_{18}), octyl (C_8), phenyl, or butyl (C_4) groups that are attached to a support such as silica. Alternative materials such as porous graphite, fluorinated hydrocarbons, and hydrophobic stationary phases with embedded polar groups can also be used. Silica tends to dissolve slowly at a pH greater than 8 or at a pH below 2, so separations that make use of silica supports

are usually done in this pH range. Some of the other supports used in reversed-phase chromatography, such as polystyrene or porous graphite, are stable over a broader pH range (e.g., pH 2 to 13).

Ion-Exchange Chromatography

Ion-exchange chromatography (IEC) is a type of LC in which ions are separated by their adsorption onto a support that contains fixed charges at its surface (see Fig. 12.11). Depending on the charge of the groups that make up the stationary phase, the types of ions that bind to the column may be either cations (i.e., positively charged ions) or anions (i.e., negatively charged ions). These two methods are referred to as **cation-exchange chromatography** and **anion-exchange chromatography**, respectively.

Supports for cation-exchange chromatography contain negatively charged groups. These groups may be the conjugate bases of strong acids, such as sulfonate ions that are formed by the deprotonation of sulfonic acid, or the conjugate bases of weak acids, such as those produced from carboxyl or carboxymethyl groups. The supports used in anion-exchange chromatography are usually the conjugate acids of strongly basic quaternary amines, such as triethylaminoethyl groups, or the conjugate acids of weak bases, such as aminoethyl (AE) or diethylaminoethyl (DEAE) groups. Supports that can be modified to contain these charged groups include silica, polystyrene, and carbohydrate-based materials such as agarose or cellulose.

A strong mobile phase in IEC is usually a mobile phase that contains a high concentration of competing ions. A weak mobile phase is one that contains few or no competing ions, or that otherwise promotes binding by charged analytes to the column. The retention of ions in this method may also be affected by (1) pH, (2) the type of competing ion that is used, (3) the type of fixed charges that are used as the stationary phase, and (4) the density of these fixed charges on the support.

IEC has a number of clinical applications. Examples are the separation and analysis of amino acids and hemoglobin variants. IEC is also frequently used as a preparative tool for purifying proteins, peptides, and nucleotides. A modified form of IEC known as *ion chromatography* can be used with a conductivity detector to analyze small inorganic and organic ions.

Size-Exclusion Chromatography

Size-exclusion chromatography (SEC) is an LC technique that separates analytes based on size (see Figs. 12.11 and 12.12). In this method, a porous support is used that has an inert surface with little or no interactions with the sample components. This support should also have a range of pore sizes that are similar to the sizes of the compounds that are to be separated. As a sample travels through this type of column, small sample components can enter all or most of the pores while larger components may enter only a few or none of the pores. The result is a separation based on size or molar mass, in which the larger components elute first from the column.

Fig. 12.12 General principle of size-exclusion chromatography. This method separates compounds based on their size by using a column that contains a porous support. (Modified from Bennett, T. P. [1968]. *Graphic biochemistry*, vol. 1: *chemistry of biological molecules*. New York: Macmillan.)

Many types of porous supports have been used in SEC. Cross-linked carbohydrate-based supports like dextran and agarose are often used for work with aqueous-based samples and biological compounds such as proteins or nucleic acids. Polyacrylamide gel and modified silica or glass beads can also be used for aqueous samples and biological compounds. Polystyrene is usually employed as the support when SEC is to be used with synthetic polymers and samples that are present in organic solvents. For each of these supports, the range of pore sizes that are present will determine the sizes of the injected compounds that can be separated.

The mobile phase in SEC can be a polar solvent, such as water, or a nonpolar solvent, which is usually tetrahydrofuran. Because the stationary phase is based on a physical difference in the accessible pore volume for the solutes, rather than being based on chemical interactions, there is no weak mobile phase or strong mobile phase in this method. The choice of the mobile phase is instead determined by the solubility and the stability of the analytes and of the support and the column. If water or an aqueous mobile phase is used in SEC, the resulting method is often called *gel filtration chromatography*. If an organic mobile phase is used, the size-exclusion method is referred to as *gel permeation chromatography*.

SEC in the form of gel filtration is useful for identifying intact complexes of agents such as lipoproteins, antibody-antigen complexes, and the binding of proteins with their target compounds. SEC is also often used to exchange buffers, to remove salts from large sample components, or to remove small molecules from large biomolecules (e.g., the isolation of drugs, fatty acids, and peptides from proteins). In addition, SEC can be used to estimate the molecular weight of a biomolecule, such as a protein

Fig. 12.13 General mechanism of separation in affinity chromatography. The target analyte is first allowed to bind to the immobilized affinity ligand in the column. After the nonretained sample components have been washed from the column, the retained analyte is later released by using an elution buffer. This elution may be based on a nonspecific method (e.g., the addition of a chaotropic agent or a change in pH), or it may be accomplished by adding a biospecific competing agent to the mobile phase to displace the analyte from the column.

or nucleic acid, or to characterize the distribution of molecular weights for a polymer.

Affinity Chromatography and Chiral Separations

Affinity chromatography (AC) is an LC method that makes use of biologically related interactions for the retention and separation of chemicals (see Figs. 12.11 and 12.13). This method uses the selective, reversible interactions that are found in many biological systems, such as the binding of an antibody with an antigen or the interactions of an enzyme with a substrate or inhibitor. This type of binding is used in AC by immobilizing one of a pair of interacting compounds onto a support for use as the stationary phase. This immobilized agent is called the *affinity ligand* and creates a column that can bind and capture the complementary compound from samples.

AC is usually carried out by applying a sample to the column under conditions that allow strong and specific binding of the affinity ligand to its target compound. This is done in the presence of an application buffer, which mimics the pH and natural or preferred conditions for binding between the affinity ligand and the target. As the target binds to the column under these conditions, most other sample components are washed away. The retained target is then later released by using an elution buffer that either contains a competing agent that will displace the target from the affinity ligand or that uses a change in conditions such as pH, ionic strength, or polarity of the mobile phase to decrease the strength of binding between the target and affinity ligand. After the target has been eluted for detection or further use, the application buffer can be passed again through the column and the system is allowed to regenerate prior to the application of the next sample. For systems with weak-to-moderate binding strengths, it is also possible to use isocratic elution for both

sample application and target elution. This second type of elution is usually employed in chiral separations.

There are various types of AC. Bioaffinity chromatography is the most common type of AC and involves the use of a biological binding agent as the affinity ligand. Examples of bioaffinity chromatography are the purification of an enzyme by using an immobilized inhibitor, and the use of lectins (i.e., nonimmune system proteins that can bind carbohydrate residues) such as concanavalin A for the isolation of glycopeptides, glycoproteins, and glycolipids. Immunoaffinity chromatography (IAC) is a type of bioaffinity chromatography that uses an antibody or antibody-related agent as the affinity ligand. The selectivity of this method has made it popular for the isolation and analysis of many targets, as well as a tool for sample pretreatment prior to analysis by other methods.

Another group of methods in AC are those that use non-biological binding agents. Immobilized metal-ion affinity chromatography (IMAC) is a method in which the affinity ligand is a metal ion, such as Ni^{2+} , that is complexed with an immobilized chelating agent. This technique is frequently used to isolate recombinant histidine-tagged proteins and has been used for the isolation or analysis of phosphorylated proteins in proteomics. Boronate affinity chromatography uses an affinity ligand that is boronic acid or a related derivative, which is useful in binding to compounds that contain *cis*-diol groups such as polysaccharides, glycoproteins, and catecholamines. An important clinical application of boronate AC is its use in the analysis and isolation of glycosylated hemoglobin in blood from diabetic patients.

Many biological molecules (including amino acids, peptides, and proteins) occur as stereoisomers, or in specific chiral forms. As a result, it is not unusual for the different chiral forms of a drug (or enantiomers) generally have identical physical and chemical properties and cannot be separated by most types of chromatography, which tend to use non-stereoselective (or achiral) stationary phases. However, it may be possible to separate the enantiomers and stereoisomers of a drug or target compound if the stationary phase is also chiral and can interact with these compounds in a stereospecific manner. This type of medium is known as a **chiral stationary phase (CSP)**. Carbohydrates, peptides, enzymes, and other proteins have all been used as CSPs. Cyclodextrins, which are cyclic polymers of glucose, are an important set of carbohydrates that have been used for separating many types of chiral compounds in both LC and GC.

Hydrophilic Interaction Liquid Chromatography and Mixed-Mode Methods

There are a number of LC methods that combine several separation modes. One example is **hydrophilic interaction liquid chromatography (HILIC)**. HILIC is a type of partition chromatography that uses a polar stationary phase, and in which chemicals partition between an organic-rich region in the mobile phase and a more polar water-enriched

layer that is at or near the surface of a polar support. The surface of the support, which can often undergo hydrogen bonding or dipole-related interactions with the applied solutes, may also have charged groups that can interact with these compounds. These features make HILIC a variation of normal-phase chromatography that is combined with some of the characteristics of reversed-phase chromatography and IEC. HILIC and related methods have become popular in areas such as proteomics and glycomics. Advantages of these methods include (1) their ability to give better separations for polar compounds than can be obtained by reversed-phase chromatography, (2) the greater ease with which they can be used with aqueous samples and in solubilizing polar compounds compared with normal-phase chromatography, and (3) the ability to couple these methods with mass spectrometry.

Ion-pair chromatography (IPC) is a technique that combines columns that are used in reversed-phase chromatography with the ability to separate ionic compounds based on their charges, as is done in IEC. This method is carried out by adding an ion-pairing agent to the mobile phase for a reversed-phase column. The ion-pairing agent is usually a surfactant that has a charged group at one end and a nonpolar tail or group at the other end. The purpose of the ion-pairing agent is to combine with ions of the opposite charge in the sample, thus also allowing their retention on the reversed-phase column through the ion-pairing agent's nonpolar tail or through the formation of a neutral complex. IPC is useful in separating charged compounds that are poorly resolved by IEC. Applications of IPC include the separation and analysis of catecholamines, drugs, and nucleic acids.

Liquid Chromatography Instrumentation

Mobile Phase Reservoirs and Delivery Systems

The major components of a system used in HPLC are shown in Fig. 12.14. The mobile phases in LC are contained in solvent reservoirs, which are often glass bottles or flasks into which “feed lines” to the pump are inserted. Filters are often placed at the inlets of these feed lines to prevent any particles in the mobile phase from moving on to the rest of the system. Most mobile phase reservoirs also have a means of “sparging” the mobile phase by bubbling through a gas such as helium or nitrogen to remove dissolved air or oxygen that may interfere with the response of some detectors. The removal of air and oxygen, or “degassing,” can also be achieved by applying a vacuum to the reservoir by placing gas exchange devices or gas filters in the flow path leading from the reservoir. Degassing the mobile phase is important to avoid dissolved gases coming out of solution and forming bubbles as the pressure drops from the column to the detector.

The composition and “strength” of the mobile phase are factors that can be used to adjust and control a separation in LC. If the same mobile phase is used throughout the separation, this approach is known as **isocratic elution**. If the composition of the mobile phase is varied over time, the method is called **solvent programming** or gradient elution (Fig. 12.15). Solvent programming begins with a weak mobile phase, to allow chemicals with weak retention to interact with the column,

Fig. 12.14 General design of a liquid chromatograph, as used in high-performance liquid chromatography. (Modified from a figure courtesy Restek Corporation, Bellefonte, PA.)

Fig. 12.15 Examples of isocratic elution (i.e., constant mobile phase composition) or linear gradient elution based on solvent programming (i.e., varying mobile phase composition).

and then goes to a stronger mobile phase to elute chemicals with moderate or high retention. This change in the mobile phase can be made in one or more steps and may involve a linear or nonlinear change over time.

Several types of pumps have been used in LC. Peristaltic and diaphragm-type pumps can be used with columns that are operated at low pressures, as are encountered in classic and low-to-medium performance LC. Reciprocating pumps and syringe pumps are used to achieve the higher pressures that are needed to deliver the mobile phase in HPLC. Reciprocating pumps are used at flow rates in the mL/min range and have a piston that moves in and out of the solvent chamber, with check valves being used to keep the flow of the mobile phase moving from the pump inlet to the outlet. The reciprocating action of the piston does generate some pulsation in the pressure and mobile phase flow, which can increase the baseline noise at the detector but can be minimized by electronic control of the pump and by placing pulse dampers in the flow path. Syringe pumps use a solvent chamber in a syringe to continuously deliver the mobile phase to the rest of the system. These pumps can deliver essentially pulse-free flow and can be used at much lower flow rates than reciprocal pumps (e.g., flow rates in the $\mu\text{L}/\text{min}$ range).

Injection Systems and Sample Derivatization

Various approaches can be used to introduce a sample into an LC system. Important characteristics to consider when selecting an injection system are its (1) reproducibility, (2) the amount of sample carryover from one injection to the next, and (3) the range of volumes that can be injected. The most widely used approach in HPLC is a fixed-loop injector that is switched into or out of the flow path by manual control or through the use of an autoinjector.

TABLE 12.3 Typical Column Sizes Used in Analytical High-Performance Liquid Chromatography

Type of Column	Typical Inner Diameter (I.D.) and Lengths	Typical Flow Rate Range
Conventional packed column	4–5 mm I.D. × 5–30 cm	1–3 mL/min
Narrow bore column	2–3 mm I.D. × 5–15 cm	0.2–0.6 mL/min
Microbore column	1–2 mm I.D. × 10–100 cm	0.05–0.2 mL/min
Packed capillary	0.1–0.5 mm I.D. × 20–200 cm	0.1–20 μ L/min
Open tubular column	0.01–0.075 mm I.D. × 1–100 cm	0.05–2 μ L/min

Portions of the data in this table are based on Poole, C. F., & Poole, S. K. (1991). *Chromatography today*. New York: Elsevier.

Derivatization is sometimes used in LC to improve the response of compounds to the detector. It is also possible to use derivatization in LC to alter the retention of a compound on the column. There are two main ways of carrying out derivatization in LC: (1) precolumn derivatization and (2) postcolumn derivatization. Precolumn derivatization is done before the sample is injected and can be used to alter a compound's retention or to increase the signal it generates at the detector. Postcolumn derivatization is carried out online as compounds elute from a column and is used only to improve the response of the detector to those compounds.

Columns and Supports

The columns in LC can have various combinations of packing materials and diameters or lengths. In the clinical laboratory, most packed HPLC columns are made of tubes based on stainless steel or pressure-resistant polymers with internal diameters that range from 4 to 5 mm and lengths that range from 5 to 30 cm (Table 12.3). An inlet filter may be present to remove particulate matter, and a short guard column that contains the same packing material may be placed before the longer analytical HPLC column to protect and extend the usable life of the HPLC column.

Better efficiencies and lower detection limits are achieved with HPLC columns that have longer lengths and smaller inner diameters, including narrow bore columns (with approximate inner diameters of 2 to 3 mm) and microbore columns (with approximate inner diameters of 1 to 2 mm). These small-diameter columns may also require lower flow rates and smaller volumes of the mobile phase for their operation than the longer conventional packed columns. Capillary columns may also sometimes be used in LC for work with flow rates in the mid- to low μ L/min range.

The most common type of support in LC is a packed bed of small particles, which are usually porous supports with diameters in the range of 1.8 to 10 μ m. A smaller diameter for these supports, as is used in UPLC, provides better efficiency but also leads to an increase in back pressure across the column.

Low to medium performance separations, which have much lower operating pressures than HPLC, typically use packing materials such as cross-linked dextran or agarose, which consist of particles with diameters of 50 to 200 μ m.

When using porous support particles, the mobile phase flows around the support but not through the particle. This means compounds must travel within the particle by means of diffusion, which is a relatively slow process that can be a major source of band-broadening. The distance that these compounds must diffuse can be reduced by using a nonporous support or a pellicular support, in which the latter has a thin porous layer or porous shell. Another approach for minimizing this band-broadening is to use perfusion particles. This support has small pores that contain most of the stationary phase and larger pores that allow the mobile phase to pass both through and around the support particles. Another alternative support that can be used to improve efficiency is a monolithic support, which consists of a continuous porous bed that is usually prepared from silica or an organic polymer.

Temperature Control

The control of column temperature can be an important factor in determining the reproducibility and efficiency of an LC separation. Temperature control of an LC column can be achieved by using temperature-controlled column chambers, water jackets, blankets, and heating/cooling blocks.

Liquid Chromatography Detectors

There are many types of detectors that can be used in LC (Table 12.4). A key component for most of these detectors is the flow cell through which the mobile phase and eluting compounds from the column must pass to provide a response. A postcolumn reactor may also be present between the column and detector to derivatize some of the eluting compounds and to generate products that give a stronger and more specific signal at the detector.

Absorbance detectors. The absorption of ultraviolet (UV) or visible (vis) light is often used to detect compounds as they elute from an LC column. Many of the absorbance detectors that are used in LC can measure the absorption of UV light wavelengths in the range of 190 to 400 nm or of visible light in the range of 400 to 700 nm. Many organic compounds with aromatic groups or double or triple bonds absorb light between 250 and 300 nm. Other organic compounds, such as those containing amide bonds or carboxylic acids, can absorb in the range of 190 to 220 nm. In addition, some ions, inorganic compounds, and metal complexes can be detected by their absorption of light in the UV or visible range.

There are several types of absorbance detectors that can be used in LC. Fixed-wavelength absorbance detectors have the simplest design and are used to monitor absorbance at a particular wavelength or wavelength band. A variable-wavelength absorbance detector has a more flexible design that can operate at a wavelength that is selected from a broad wavelength range. A photodiode array detector (PDA) is an absorbance detector that uses an array of small detector cells to measure the change in absorbance at many wavelengths simultaneously, which can

TABLE 12.4 Examples of Detectors Used in Liquid Chromatography

Type of Detector	Principle of Operation	Range of Application	Detection Limit
Absorbance detector	Measures absorbance of light at a given wavelength or set of wavelengths	Compounds with chromophores that can absorb ultraviolet or visible light	10^{-10} – 10^{-9} g
Fluorescence detector	Measures ability of chemicals to absorb and reemit light through fluorescence	Compounds with fluorophores	10^{-12} – 10^{-9} g
Electrochemical detector	Measures current or charge as a result of chemical oxidation or reduction	Electrochemically active compounds	10^{-11} – 10^{-9} g
Conductivity detector	Measures change in conductivity of the mobile phase as ions elute from the column	General for ionic solutes	10^{-9} g
Refractive index detector	Measures change in refractive index of the mobile phase as compounds elute the column	Universal	10^{-7} – 10^{-6} g
Mass spectrometry	Production of gas phase ions, followed by separation/analysis of these ions based on their mass-to-charge ratios	Universal—full-scan mode Selective—selected ion monitoring (SIM) mode	10^{-10} – 10^{-9} g (Full-scan mode) 10^{-12} g or lower (SIM mode)

Portions of the data in this table are based on Poole, C. F., & Poole, S. K. (1991). *Chromatography today*. New York: Elsevier.

be valuable in identifying overlapping peaks or in identifying analytes in complex samples such as urine and serum.

The use of an absorbance detector requires solvents and mobile phase components that have little or no absorption of light at the wavelengths of interest. Effective degassing of the mobile phase is important to minimize bubble formation, which can interfere with absorbance measurements. The use of some back pressure across the detector can further reduce bubble formation. However, care must be taken with this approach to avoid exceeding the usable pressure range of the detector.

Fluorescence detectors. Fluorescence detectors measure the ability of a chemical to absorb light at one wavelength and reemit the light at a different, longer wavelength. Fluorescence detectors in LC are generally much more selective and have better limits of detection than absorbance detectors for chemicals that are naturally fluorescent or that can be converted into a fluorescent derivative. Both precolumn and postcolumn derivatization have been used to modify chemicals (e.g., amino acids, peptides, and proteins) for this type of detector.

Electrochemical and conductivity detectors. The combination of an electrochemical detector with LC is often known as **liquid chromatography–electrochemical detection (LC-EC)**. In an amperometric electrochemical detector (see Chapter 10), an electroactive chemical that enters the flow cell may be oxidized or reduced at an electrode that is held at a constant potential. The current needed for or generated by this process is then measured, with the magnitude of the current being proportional to the concentration of the analyte. Electroactive compounds of clinical interest and that can be examined by this process include catecholamines, ascorbic acid, and thiol-containing compounds such as homocysteine. In addition, electrochemically active tags (e.g., bromine) can be added to compounds such as unsaturated fatty acids or prostaglandins for use with this type of detector.

Coulometric detectors measure the amount of charge that is required for a given electrochemical reaction. These detectors are selective, sensitive, and have reasonably wide linear ranges. Coulometric detectors are used in clinical laboratories for the analysis of metanephrines, vanillylmandelic acid, homovanillic acid, and 5-hydroxyindole acetic acid in human urine.

A conductivity detector measures the ability of the mobile phase and its contents to conduct a current when they are placed in an electrical field. This type of detector is often used in combination with IEC to monitor salt gradients, or in ion chromatography to monitor the elution of charged analytes. Conductivity detectors have been used to measure compounds such as sulfate in biological fluids.

Refractive index detectors. A refractive index (RI) detector in LC measures the change in the refraction of light as chemicals pass within the mobile phase through a flow cell. An important advantage for this type of detector is that it can monitor substances such as alcohols, salts, and sugars that do not absorb light at usable wavelengths or fluoresce. One disadvantage of this type of detector is it does not have limits of detection as low as absorbance or fluorescence detectors, and it has a response that can be sensitive to changes in the mobile phase composition and temperature.

Mass spectrometry. LC can be combined with mass spectrometry, giving a combined technique known as **liquid chromatography–mass spectrometry (LC-MS)**. This combination makes it possible to both measure chemicals and to identify them based on the masses of their molecular ions or fragment ions. When used in the full-scan mode, the mass spectrometer in LC-MS acts as a general detector. If the mass spectrometer is instead used for looking at particular ions, this device then acts as a selective detector. It is also possible to add another dimension based on mass spectrometry, as occurs in liquid chromatography–tandem mass spectrometry (LC-MS/MS), to look at fragment ions that are produced from a given precursor ion. This addition can further increase

Fig. 12.16 General operation and system components of thin-layer chromatography. In this particular example, the mobile phase moves up the glass plate and a thin layer of adsorbent by means of capillary action. (Modified from Bennett, T. P. [1968]. *Graphic biochemistry, vol. 1: chemistry of biological molecules*. New York: Macmillan.)

the ability of the method to resolve or detect multiple components and can enable the analysis of hundreds or thousands of components in a sample.

Several types of ionization methods and mass analyzers can be employed in LC-MS (see Chapter 13). A common combination is the use of electrospray ionization with a quadrupole mass analyzer. Other possible ionization methods that can be used are CI or photoionization. The interface in LC-MS has to remove solvent from the mobile phase and place the sample components in a charged form in the gas phase that can be analyzed by the mass spectrometer. This process requires that the buffers used in LC-MS be sufficiently volatile to avoid overloading and contaminating the interface.

Data Acquisition and System Control

The system controller for an HPLC will often manage (1) sample injections, (2) solvent delivery, (3) the system flow rate and temperature, as well as (4) control the detectors, and (5) acquire data from these detectors. Data acquisition systems can collect thousands of data points from an individual run. These data can then be used to identify and measure the eluting compounds based on the retention times and areas or heights of their peaks. The hardware and software that are used for data analysis can become particularly important as the amount of collected data becomes large, as can often occur with the use of a PDA or LC-MS. Libraries of spectra or other databases can be searched to aid in the identification of chemicals based on the chromatograms and signals that are generated during the separation.

PLANAR CHROMATOGRAPHY

In planar chromatography, the stationary phase is coated or placed onto a flat surface, or plane. The sample is added as a small spot or band on this surface. This support is then placed into an enclosed container with one edge in contact with the mobile phase and the sample band located just beyond this point of contact (Fig. 12.16). The mobile phase is usually allowed to travel across the plane by means of capillary action. After this movement has occurred for a given period

Fig. 12.17 General example of a separation obtained by planar chromatography. In this example, compound B is more strongly retained and migrates a shorter distance than compound A. D_s , Distance travelled by an analyte (A, in this example) from the point of sample application; D_f , distance travelled by the mobile phase, or solvent front, from the point of sample application in the same amount of time as allowed for sample migration.

of time, the support is removed from the mobile phase and dried prior to the analysis or measurement of the separated sample components.

The planar surface that is used in this method may be a sheet of paper, known as *paper chromatography*, or some other type of surface, resulting in a method known as *thin-layer chromatography* (TLC). In paper chromatography, the stationary phase is the surface of the paper or a layer of a solvent or chemical that is coated or placed onto the paper. In TLC, a thin layer of particles (such as silica or alumina) is spread on a glass plate, plastic sheet, or aluminum sheet.

In planar chromatography, retention is described by the distance that compounds have traveled in a given amount of time (Fig. 12.17), rather than the time or volume of mobile phase required for elution, as is used in column chromatography. The distance traveled by a chemical from its point of application (D_s) in paper chromatography and TLC is often compared with the distance that has been traveled by the mobile phase in the same amount of time (D_f). This information can be used to calculate a measure of retention that is known as the **retardation factor** (R_f).

$$R_f = D_s/D_f$$

The value for R_f will always be between zero and one. Chemicals that have high retention with the stationary phase will have low values R_f , and chemicals that have low retention will have R_f values that approach one. Chemicals can be identified in planar chromatography by comparing their retention and R_f values with those for reference compounds that have been examined on the same stationary phase and support and mobile phase. The detection characteristics of the reference compounds can also be compared with the chemicals in the unknown sample (e.g., the color of their bands or their response to a color-forming reagent). Additional confirmation can be obtained by comparing the unknown compound and the reference compound under a different set of separation conditions.

The separated components in planar chromatography can often be detected by their natural color, by their response to

UV light or through their fluorescence, or by their visualization with reagents that form colored products. In some cases, these chemicals may be allowed to react with labeled antibodies for their detection, or they may be detected by using radio-labels and autoradiography. Their bands may also be removed from the planar surface for analysis by a method such as mass spectrometry or nuclear magnetic resonance spectroscopy.

Paper chromatography and TLC tend to be used primarily for qualitative analysis. One application of these techniques is their use in the analysis of amniotic fluid to determine lecithin-to-sphingomyelin ratios. Another application is in the screening of urine for drugs or metabolites such as amino acids that accumulate during hereditary disorders.

REVIEW QUESTIONS

- Which component in a chromatographic system carries the sample?
 - Stationary phase
 - Mobile phase
 - Support
 - Column
- Which of the following is *not* an approach that can be used to improve the separation of two compounds by a chromatographic system?
 - Increase the degree of peak retention
 - Increase the selectivity of the system for one compound versus another
 - Increase the amount of sample that is applied
 - Increase the efficiency of the system
- In column chromatography, unknown analytes are identified as they pass through the detector. Comparison of the _____ of unknown analytes with that of standard compounds can be used for identification of the analytes.
 - separation factor
 - retention factor
 - resolution
 - plate height
- Before it can be used in a separation by GC, a compound must:
 - be volatile or be converted into a volatile form.
 - not be volatile.
 - be water soluble.
 - be present in a large quantity in a sample.
- Which type of GC might use alumina particles as the stationary phase?
 - Gas-liquid chromatography
 - Gas-solid chromatography
 - Bonded phase gas chromatography
 - Capillary gas chromatography
- Which of the following common detectors for GC can be used in more than one mode to either detect many compounds or examine specific analytes?
 - Nitrogen-phosphorus detector
 - Electron capture detector
 - Mass spectrometer
 - Flame ionization detector
- Which of the following statements concerning LC is *not* correct?
 - HPLC is the form of LC used in most routine chemical separation or analysis methods.
 - Normal-phase chromatography uses a nonpolar stationary phase and is one of the most popular types of LC.
 - Cation-exchange chromatography uses negatively charged groups as the stationary phase.
 - A porous support is used in size-exclusion chromatography.
- Some point-of-care tests use chromatography as a processing step in the assay. In point-of-care pregnancy testing, for example, the stationary phase is nitrocellulose paper and the hCG antigen is present in a urine sample, which is considered the mobile phase. The antigen in the mobile phase binds with an antibody in the stationary phase. This is an example of planar chromatography using which of the following as the separation mechanism?
 - Partition chromatography
 - Ion-exchange chromatography
 - Size-exclusion chromatography
 - Affinity chromatography
- Which statement is true about the mobile phase in LC?
 - The strength of the mobile phase is varied during solvent programming.
 - A strong mobile phase gives strong retention for compounds on an LC column.
 - An organic solvent is a weak mobile phase in reversed-phase chromatography.
 - The mobile phase has few interactions with the injected compounds in LC.
- Which of the following statements is *not* true about planar chromatography?
 - Compounds may be identified by using their retardation factors.
 - Paper may be used as a support in this method.
 - This method is mainly used for quantitative analysis.
 - Thin-layer chromatography is one form of this method.

OBJECTIVES

1. Define the following terms:
 - Base peak
 - Ion trap
 - Mass analysis
 - Mass spectrometry
 - Mass-to-charge ratio (m/z)
 - Molecular ion
 - Product ion
 - Fragment ion
 - Quadrupole
 - Triple quadrupole
 - Tandem mass spectrometry
 - Time of flight (TOF)
 - Ion trap
 - Matrix-assisted laser desorption/ionization (MALDI)-TOF
2. Describe the main components of a mass spectrometer (MS), their functions, and principles of operation.
3. For the following ionization methods, state the principle and specific uses of each type:
 - Electron
 - Chemical
 - Electrospray
 - Atmospheric pressure chemical
 - Inductively coupled plasma (ICP)
 - MALDI
4. State the principles of operation of quadrupole, triple quadrupole, ion trap, and TOF mass analyzers.
5. List types of commonly used electron multiplier detectors and state the principle of this type of detection.
6. Explain the role of mass spectrometry in clinical laboratories.

KEY WORDS AND DEFINITIONS

Base peak An ion with the highest abundance in the mass spectrum; it is assigned a relative abundance of 100%.

Electrospray ionization Using this ionization technique, a sample is passed through a capillary to which a high voltage is applied, resulting in expulsion of ions from a spray of fine droplets.

Extracted ion chromatogram A plot consisting of a sum of selected mass-to-charge ratios displayed as a function of time.

Fragment ion An ion formed by fragmentation of a molecular ion.

Gas chromatography–mass spectrometry (GC-MS) A technique that uses a gas chromatograph coupled to a mass spectrometer.

Internal standard A structural analog of a substance that is added to calibrators, controls, and unknown samples at a constant amount. An internal standard corrects for variable recovery between samples during the sample preparation and analysis steps. The internal standard should have similar physical and chemical properties to the targeted molecule, with a distinct mass spectrometry

signal. Internal standards typically contain stable isotopes of atoms.

Ion An atom or a molecule that has acquired an electrical charge by losing or gaining one or more electrons or other charged species such as protons.

Ionization Required for all mass spectrometry techniques; “ionization” describes the production of ions from neutral atoms or molecules using various techniques including but not limited to electron ionization, chemical ionization, or electrospray ionization.

Ion trap Type of mass analyzer in which ions are held in a spatially confined region using, for example, a magnetic or electrostatic field. Manipulation of the trap allows m/z measurements to be performed, as well as fragmentation of the molecular ion to allow multiple levels of the fragmentation (MS_n).

Isotope A variant of a chemical element; each variant differs in the number of neutrons in the nucleus and therefore in atomic weight.

*The authors gratefully acknowledge the original contributions by Thomas M. Annesley and Nicholas E. Sherman on which portions of this chapter are based.

Isotope dilution mass spectrometry (IDMS) An analytical technique used to quantify a compound relative to isotopic analogs added to samples as internal standards at fixed concentrations.

Liquid chromatography–mass spectrometry (LC-MS) A technique that uses a liquid chromatograph coupled to a mass spectrometer.

Mass-to-charge ratio (m/z) The ratio formed by dividing the molecular mass of an ion by its charge.

Mass analysis The process of resolving ionic species based on their mass-to-charge ratios.

Mass spectrometer An analytical instrument that ionizes atoms or molecules; separates the ions and detects the m/z of these ionized atoms or molecules or their ion fragments. Mass spectrometers are often interfaced with other instruments including but not limited to a second mass spectrometer, a liquid chromatograph, or a gas chromatograph.

Mass spectrometry (MS) Study of matter through the formation of gas-phase ions that are characterized by their mass, charge, structure, and/or physicochemical properties.

Mass spectrum A plot of the relative abundance of ions plotted as a function of their mass-to-charge ratio.

Matrix-assisted laser desorption/ionization (MALDI) A soft ionization technique allowing analysis of organic molecules (proteins, peptides, DNA, polysaccharides), and microorganisms. MALDI ionization is performed by irradiation of sample mixed with a matrix using pulsed laser.

Product ion A fragment ion formed when a molecular ion breaks into smaller pieces. In a tandem mass spectrometer, the fragmentation process takes place after molecular ions have been separated by their m/z value in the first stage.

Selected ion monitoring (SIM) A mass spectrometry technique where signal from only specified ions of interest are acquired.

Tandem mass spectrometer A mass spectrometer capable of multistage separation of ions in an ion beam based on the m/z values (tandem in space) or separation of trapped ions according to m/z values (tandem in time).

Torr A non-SI unit of pressure with 760 torr equal to 1 standard atmosphere. One torr is essentially equal to the pressure exerted by a millimeter high column of mercury.

Total ion chromatogram (TIC) A chromatogram created by summing up intensities of all m/z responses acquired by a mass analyzer during chromatographic separation. The chromatogram is displayed as a function of time.

BASIC CONCEPTS

A **mass spectrometer** is an analytical instrument that ionizes molecules and then separates and measures the **mass-to-charge ratio (m/z)** of the ionized molecules and their fragments. **Mass analysis** is the process of identification of the m/z ratios of the ions. This analysis may be qualitative, or it may be both qualitative and quantitative. **Mass spectrometry (MS)** is useful for identifying and determining elemental composition and structure of compounds, as well as for performing quantitative analysis of components of samples.

A **mass spectrum** is represented by the relative abundance of **ions** plotted as a function of their m/z ratio (Fig. 13.1). When an ion has a single charge ($z = 1$) the m/z ratio is equal to the mass of the ion. The unfragmented ion of a molecule is called the *molecular ion*. **Fragment ions** are formed when a molecular ion breaks into smaller pieces. The ion with the highest abundance in the mass spectrum is assigned a relative value of 100% and is called the **base peak**. The base peak may be the molecular ion or a fragment ion. Fragmentation of ions at specific bonds depends on their chemical nature; in some cases it is possible to determine the structure of a molecule from the fragment ions present in the mass spectrum. Because patterns of relative abundance among the fragment ions of a given compound are often unique to that compound, computer-based libraries of spectra take advantage of this for identification of the analytes from the mass spectra.

In **tandem mass spectrometry** fragmentation takes place after ions have been separated by their m/z values in a first stage of mass spectrometry; these fragment ions are named **product ions**.

Mass spectrometers are often considered to be “universal detectors” because most molecules can be ionized and can therefore be detected by a MS. When interfaced with a liquid or a gas chromatograph, the MS often provides highly specific detection and structural information. In such instruments multiple mass spectra are acquired across the chromatographic peaks, and the sum of all the ions detected across the peak displayed as a function of time represents a **total ion chromatogram (TIC)**. It is possible to program the data system to display the sum of ions over a restricted mass range rather than the full mass range or multiple m/z values; the resultant chromatogram is called an **extracted ion chromatogram (EIC)** (Fig. 13.2). Both TICs and EIC are displayed as signal intensity plotted as a function of time.

For quantitative analysis when only a few analytes are of interest, and their mass spectra are known, the MS is typically setup to monitor only the ions of interest. This is known as **selected ion monitoring (SIM)**. The MS cycles repeatedly and rapidly through a list of selected m/z values, monitoring the abundance of each m/z for a specified time. Because SIM focuses only on specified ions, more ion signal is collected for each selected m/z , as compared with acquisition of the full mass spectrum, increasing the signal-to-noise ratio for the targeted analytes and improving the lower limit of detection.

Fig. 13.1 Mass spectrum of: (A) pentafluoropropionyl, and (B) carboxyhexafluorobutyl derivatives of D-methamphetamine.

By convention, an unknown is considered to be identified if the relative abundances of three or four ion fragments agree within $\pm 20\%$ of those of a reference mass spectrum.

Mass spectra of most molecules contain a series of peaks, most often differing by approximately one m/z unit, with the differing masses of the peaks attributed to the presence of atoms of different elemental **isotopes** within the molecule. These peaks are commonly referred to as isotope peaks or isotopic peaks. For example, the mass spectrum of $C_2H_7O^+$ consists primarily of three isotope peaks at nominal m/z values of 47, 48, and 49, with relative abundances of 100%, 2.4%, and 0.2%, respectively. The higher isotope peaks of $C_2H_7O^+$ contain contributions from ^{12}C , ^{13}C , 1H , 2H , ^{16}O , ^{17}O , and ^{18}O in various combinations. For example, the m/z 48 peak of $C_2H_7O^+$ is composed of $^{12}C^{13}C^1H_7^{16}O^+$, $^{12}C_2^1H_6^2H^{16}O^+$, and $^{12}C_2^1H_7^{17}O^+$ (Fig. 13.3). Calculation of isotopic patterns can be challenging, particularly for high-molecular-weight compounds. Various methods used to meet this challenge are discussed in the literature.

Molecules can be isotopically labeled by substituting atoms of a selected isotope for the naturally occurring

isotopic atoms at specified portions of the molecule. A labeled molecule can be separated from an unlabeled molecule by its mass difference. The relative abundances of labeled versus unlabeled molecules can be measured. **Isotope dilution mass spectrometry** uses this feature by adding a known amount of stable isotope-labeled **internal standard** into a sample and basing quantitative measurements on the ratio of abundance of the analyte to the abundance of the internal standard. This technique compensates for variation during sample preparation and instrumental analysis (e.g., incomplete recovery of the target analyte during sample preparation, or day-to-day variations in instrument response) and enables use of MS for quantitative analysis.

INSTRUMENTATION

All mass spectrometers include the following: (1) ion source, (2) vacuum system, (3) mass analyzer, (4) detector, and (5) computer (Fig. 13.4). In most cases, a chromatograph is used as a sample introduction device.

Ion Source

All MS techniques require an **ionization** step, in which an ion is produced from a neutral atom or molecule, or ions present in solution get transferred to the gas phase. Electron ionization (EI) and chemical ionization (CI) are techniques used when gas phase molecules are introduced directly into the mass analyzer, usually from a gas chromatograph. The ionization methods used most frequently when a high-performance liquid chromatograph is interfaced with a mass spectrometer (HPLC-MS) include (1) **electrospray ionization** (ESI) and (2) atmospheric pressure chemical ionization (APCI); other less frequently used ionization techniques are (1) atmospheric pressure photoionization (APPI), (2) inductively coupled plasma (ICP), and (3) **matrix-assisted laser desorption/ionization** (MALDI).

Electron Ionization

In EI, gas phase molecules are bombarded by electrons emitted from a heated filament (Fig. 13.5). This process must occur in a vacuum to prevent filament oxidation and collisional attenuation of the electron beam. Electrons emitted from a hot filament by thermionic emission are accelerated through a potential difference of ~ 70 V and directed orthogonal to a flow of vaporized sample. Electrons have enough kinetic energy to eject an electron from the analyte molecule, producing, in nearly every case, a radical cation. In most cases, these radical ions then undergo unimolecular rearrangements and fragmentation to produce other cations and radicals:

Positive ions are drawn out of the ionization chamber by an electrical field and introduced into the mass analyzer. The relative intensity of the molecular ion and the fragment ions is reasonably reproducible. In EI the mass spectral pattern in most cases is dominated by fragment ions and can be matched to the entries in a mass spectral library.

Fig. 13.2 A total ion chromatogram (TIC), scanning m/z between 100 and 500, is shown in the top panel, and an extracted ion chromatogram (EIC) of human serum with m/z between 415.0 and 416.0 is shown in the bottom panel. CPS, Counts per second.

Fig. 13.3 Monoisotopic and isotopic peaks of the ion $C_2H_7O^+$ and their composition. M is the monoisotopic ion $C_2H_7O^+$ composed of $^{12}C_2^{1}H_7^{16}O^+$. $M+1$ is the first isotopic ion of $C_2H_7O^+$ that could be composed of $^{13}C_1^{12}C_2^1H_6^2H^{16}O^+$, $^{12}C_2^1H_6^2H^{16}O^+$, or $^{12}C_2^1H_7^{17}O^+$. $M+2$ is the second isotopic ion of $C_2H_7O^+$ that could be composed of $^{13}C_2^1H_7^{16}O^+$, $^{12}C_1^{13}C_1^1H_7^{17}O^+$, $^{12}C_2^1H_6^2H_1^{17}O^+$, $^{12}C_2^1H_6^2H_2^{16}O^+$, or $^{13}C_1^{12}C_1^1H_7^{17}O^+$.

Chemical Ionization

CI is a “soft” ionization technique, meaning that relatively little fragmentation occurs during the ionization process. A proton is transferred to (or abstracted) from a gas phase analyte by a

Fig. 13.4 Block diagram of the components of a chromatograph-mass spectrometer system. EIC, Extracted ion chromatogram; SIM, selected ion monitoring chromatogram; TIC, total ion chromatogram.

reagent gas molecule; commonly used reagent gases are (1) methane, (2) ammonia, (3) isobutane, and (4) water. An electron beam ionizes the reagent gas and produces reactive species (e.g., CH_5^+ in the case of methane reagent gas), followed

Fig. 13.5 Electron impact ion source. The magnets are used to collimate a dense electron beam, which is drawn from a heated filament placed at a negative potential. The electron beam is positioned in front of a repeller, which is at a slight positive potential compared with the ion source. The repeller sends any positively charged fragment ions toward the opening at the front of the ion source. The accelerating plates strongly attract the positively charged fragment ions.

Fig. 13.6 Proposed mechanism of a chemical ionization process. In (A), an electron beam ionizes a reagent gas (CH_4) and produces reactive species (CH_5^+). In (B), positive ions are produced by proton transfer to an analyte molecule.

by proton transfer from CH_5^+ to the analyte molecule. CI is a low-energy process that typically results in a mass spectrum dominated by the (unfragmented) molecular ion (Fig. 13.6). Ions produced by accepting a proton are typically closed-shell ions (i.e., not radical ions). Because of the lack of fragmentation, CI is advantageous for the determination of molecular mass of the constituents of samples, and for quantification.

Another variation of CI, negative ion electron capture CI, has become popular for quantification of molecules containing electronegative functional groups (e.g., chlorine, fluorine, nitro), with formation of negative ions occurring when electrons get captured by the electronegative functional group. Since the number of compounds capable of negative ionization is relatively small, the background signal in the mass spectra is typically low, and because the entire signal corresponds to a molecular ion, negative ion CI often has lower limits of detection than EI and positive ion CI.

Electrospray Ionization

ESI is a technique in which a sample is ionized at atmospheric pressure before it is introduced into the mass analyzer. Effluent

from a chromatographic column is passed through a capillary to which 1.5 to 5 kV is applied (Fig. 13.7A). Electrostatic forces applied to the effluent result in formation of charged droplets. Often a coaxially applied nebulizing gas helps nebulize the liquid and direct the charged droplets toward a counter electrode. While droplets evaporate and shrink, the field strength on the surface increases and solvated ions get expelled from the droplets. In positive ion mode, the proton adducts of the molecule (typically clustered with solvent molecules) are “desolvated” to form “bare” ions, which then pass through an aperture inside the vacuum region of the mass analyzer.

ESI depends mainly on solution phase chemistry. Basic compounds (because they are easily protonated) tend to be efficiently detected in positive ion mode. Less commonly a positive ion is formed by adduction of some other positively charged ion, such as an ammonium ion or an alkali metal ion. In some cases, the ion may arise from a permanently charged functional group within the targeted molecule, such as a quaternary ammonium group (e.g., acylcarnitines, choline). Occasionally ionization occurs via electrochemical reactions in the ESI ion source. Acidic compounds may lose a proton to become negatively charged ions in solution, and in many applications can be efficiently detected in negative ion mode.

ESI may produce multiple charged ions from some compounds, particularly from peptides and proteins. It is common to observe approximately one charge for every ~10 amino acid residues in a protein. For example, because a molecule of mass 20,000 yields up to ~20 charges, it is detected at $m/z \sim 1000$ ($20,000/20$), which greatly extends the accessible molecular weight range of an instrument. In most cases where multiple charging occurs, a series of charge states are observed appearing at a series of m/z values (e.g., for a molecule with mass 20,000, m/z 1053.6, 1001.0, 953.4 will be observed for ions of charges +19, +20, +21, respectively). In most cases, ions are produced by proton adduction, and peaks are observed at $m/z = (M + n)/n$, where M is the molecular weight and n is the charge (equal to the number of attached protons).

Although Fig. 13.7A shows the sample introduction probe as it is being directed toward the sampling orifice of the MS, in some designs the ESI probe is offset relative to the sampling cone to enhance performance and minimize contamination of the mass analyzer.

Atmospheric Pressure Chemical Ionization

APCI (Fig. 13.7B) is similar to ESI, as it (1) takes place at atmospheric pressure, (2) involves nebulization and desolvation of ions, and (3) uses the same sampling and extraction cones as ESI. However, no voltage is applied to the inlet capillary; instead, a corona discharge needle is positioned on the path of the evaporated HPLC stream, to initiate a cascade of gas phase reactions that ionize compounds through a series of ion molecule reactions, similar to the reactions occurring in CI (Fig. 13.6), but with molecules of the mobile phase constituents (e.g., water, methanol) serving as reagent molecules. Products of these secondary reactions typically contain clusters of solvent and analyte molecules, so a heated transfer

Fig. 13.7 Schematics of (A) electrospray, and (B) atmospheric pressure chemical ionization ion sources. Note the different points where ionization occurs as described in the text.

tube or a countercurrent flow of an inert gas (e.g., nitrogen) and potential differences are used to decluster the ions. APCI is the second most commonly used ion source in methods for quantitative analysis using **liquid chromatography–mass spectrometry (LC-MS)** and LC-MS/MS instruments.

Inductively Coupled Plasma

Similar to ESI and APCI, ICP is an atmospheric pressure ionization method. However, unlike most atmospheric pressure ionization methods, which are “soft” and produce little fragmentation, ICP is the ultimate in “hard” ionization, typically leading to complete atomization of the sample. Consequently its primary use is for elemental analysis. In clinical laboratories it is useful for trace metal and heavy metal analysis in tissue or body fluids. ICP based instruments are extremely sensitive (e.g., parts per trillion) and are capable of a wide dynamic range. The sample is typically prepared by acid digestion, and is introduced into the ion source via a nebulizer fed by a peristaltic pump. The nebulized sample is transmitted into hot plasma maintained at atmospheric pressure by inductively coupling power into the plasma using a high-power radio frequency (RF) generator. A small orifice samples the plasma, and ions are transmitted to the vacuum region of a mass analyzer through a series of differential pumping stages.

ICP-MS is comparatively free from interferences. However, some interferences, such as polyatomic species formed in the torch via ion-molecule reactions, could be of the same molecular mass as the metals of interest; for example, $^{40}Ar^{35}Cl^+$, $^{59}Co^{16}O^+$, $^{36}Ar^{38}Ar^{1}H^+$, $^{38}Ar^{37}Cl^+$, and

$^{36}Ar^{39}K$ are all isobaric to ^{75}As . One approach to resolve these interferences is to use a dynamic reaction cell where a reactant gas (e.g., ammonia) is introduced after the ion source, but before the mass analyzer, causing breakdown of the polyatomic interferences.

Matrix-Assisted Laser Desorption/Ionization

MALDI is a soft ionization technique using a laser energy absorbing matrix to create ions. In order to prepare a sample for MALDI ionization, it should be mixed with a solution of matrix, typically a low-molecular-weight UV-absorbing compound, placed on a target, and dried. As the liquid evaporates, the matrix crystallizes and incorporates analyte molecules in the crystals. A pulsed laser irradiates the sample, triggering rapid vaporization and desorption of the sample and matrix material; the analyte molecules are ionized in the plume of ablated gases, and are introduced into a mass analyzer (Fig. 13.8). Because MALDI produces discrete, pulsed ion packets, it is often coupled with a time-of-flight (TOF) mass analyzer. During the last 5 years, MALDI-TOF instruments have become widely adopted in clinical laboratories for bacterial identification.

POINTS TO REMEMBER

Ionization is required for all mass spectrometry techniques. The term *ionization* describes the production of ions from neutral atoms or molecules using various techniques, including but not limited to EI, CI, and APCI, ESI, or MALDI.

Fig. 13.8 Matrix-assisted laser desorption ionization. Co-crystallized matrix and analyte are irradiated with an ultraviolet laser resulting in formation of a plume of matrix ions and analyte ions. Gas phase ions are directed into a mass analyzer.

Vacuum System

With the exception of certain **ion trap** mass spectrometers, ion separation in a mass analyzer requires that the ions do not collide with other ions and molecules during m/z analysis, requiring the use of a vacuum ranging from 10^{-3} to 10^{-9} **torr**, depending on the mass analyzer type. To reach this level of vacuum, mass spectrometers use a combination of mechanical and high vacuum pumps. The mechanical pump evacuates the system to a vacuum at which the high-vacuum pump is effective. The mechanical pump also acts as a backing pump to the high-vacuum pump. Turbomolecular pumps are the most commonly used type of high vacuum pumps in mass spectrometers.

Mass Analyzers, Ion Detectors, and Tandem Mass Spectrometers

Mass spectrometers measure mass-to-charge ratio and not mass. This has a fundamental impact on the physical operating principles of mass spectrometers and influences all aspects of (1) instrument design, (2) operation, and (3) interpretation of results.

Types of Mass Spectrometers

Mass spectrometers are broadly classified as (1) beam and (2) trapping type instruments. In beam-type instruments, ions make one trip through the instrument and are destructively detected when striking a detector. The entire process, from the time an ion enters the analyzer until the time it is detected, generally takes microseconds to milliseconds.

In a trapping-type analyzer, ions are held in a spatially confined region by a combination of magnetic, electrostatic, and/or RF electrical fields. The trapping fields are manipulated to allow m/z measurements to be performed. Trapping times vary from a fraction of a second to minutes; most applications use trapping time at the low end of this range.

Beam-type designs. Beam-type mass spectrometers include (1) quadrupole, (2) magnetic sector, and (3) TOF

instruments. It is convenient to categorize beam-type instruments into two broad categories: those that produce a mass spectrum by scanning the m/z range over a period of time (quadrupole and magnetic sector) and those that acquire successive instantaneous snapshots of the mass spectrum (TOF). This categorization is not definitive, as certain instrument designs have been adapted to either scanning or nonscanning operation. Nevertheless, the categorization is useful because it covers most of the currently available instruments, with both types of instruments used for various types of applications.

Quadrupole. Quadrupole mass spectrometers, sometimes known as *quadrupole mass filters* (QMFs), are the most widely used type of mass analyzers. Although these instruments lag behind magnetic sector instruments in terms of (1) sensitivity, (2) mass range capabilities, (3) resolution, and (4) mass accuracy, they offer a number of attractive and practical features, including (1) ease of use, (2) flexibility, (3) adequate performance for most applications, (4) relatively low cost, (5) smaller size, and (6) less critical site requirements.

A quadrupole mass spectrometer consists of four parallel electrically conductive rods arranged in a square array (Fig. 13.9). The beam enters near the axis at one end of the array, passes through the array in a direction parallel to the axis, and exits at the far end of the array. The ion beam entering the quadrupole array may contain a mixture of ions of various m/z values; by adjusting voltages applied to the quadrupoles and the lenses, it is possible to allow ions of a narrow m/z range (typically $\Delta m/z < 1$) to be transported through the device to reach the detector. Ions with m/z outside this narrow range are ejected radially. The $\Delta m/z$ range represents a passband, analogous to the bandwidth of an interference filter in optics. This is why quadrupole mass spectrometers in the past were referred to as “mass filters.”

The principle of operation of quadrupole mass spectrometers is based on a superposition of RF and direct current (DC) potentials applied to the rods. DC voltages are applied to the electrodes in a quadrupolar pattern. For example, a positive DC potential is applied to electrodes 1 and 3, as indicated in Fig. 13.9, and an equivalent negative DC potential is applied to electrodes 2 and 4. The DC potentials are relatively small, on the order of a few volts. Superimposed on the DC potentials are the RF potentials, also applied in a quadrupolar fashion. The RF potentials range up to the kilovolt range and a frequency of ~ 1 MHz, which is typically fixed to a constant value.

The device may be operated in a selected ion monitoring mode (SIM) or in a scanning mode. In an SIM mode, both DC and RF voltages are set to allow the center of the passband to be transmitted through the ion path. For example, the mass spectrometer may be set to pass ions of $m/z\ 363 \pm 0.5$; both the center m/z and the $\Delta m/z$ are adjusted by the appropriate choice of DC and RF and establishes the passband ($\Delta m/z$) and the resolution $[(m/z)/(\Delta m/z)]$.

In general, quadrupole instruments are limited to a resolution of up to several thousand. Because of the relatively small

Fig. 13.9 Diagram of quadrupole mass filter, showing (A) direct current and (B) radio frequency voltages applied to a quadrupole rod assembly.

Fig. 13.10 Diagram of time of flight mass analyzer.

size and simplicity of operation, quadrupole mass analyzers are commonly interfaced with gas and liquid chromatographs.

Time of flight. TOF mass spectrometers are widely used and offer a number of advantages, including (1) nearly unlimited m/z range, (2) high acquisition speed, (3) high mass accuracy, (4) moderately high resolution, (5) high sensitivity, (6) absence of peak skew in the mass spectrum, and (7) reasonable cost. They are well adapted to pulsed ionization sources, which is an advantage in some applications, particularly with MALDI and related techniques.

Modern TOF mass spectrometers (TOF-MS) are capable of single-digit parts per million (ppm) mass accuracy, which in some cases may allow to confirm the compound's molecular formula. TOF-MSs are conceptually simple to understand, as they are based on a principle that a lighter ion travels faster than a heavier ion, provided that both have the same kinetic energy. A TOF-MS resembles a long pipe (Fig. 13.10); ions are created or injected at the source end of the pipe and accelerated by a potential of several kilovolts. The ions travel down the flight tube and strike the detector at the far end of the flight tube. The time it takes to traverse the tube is known as the *flight time*, which is related to the m/z of the ion, and is proportional to the square root of the m/z ratio.

To accurately capture such transitory signals, the data recording system must operate on a nanosecond time scale. Advances in signal processing electronics have made TOF-MS practical at relatively modest costs, and this has been a major factor in the rise in popularity of TOF mass analyzers.

TOF-MS is often used with continuous flow ion sources (ESI), but because it is inherently a pulsed technique, it couples readily to pulsed ionization sources, with MALDI being the most common type. MALDI-TOF makes its biggest impact in the area of protein, peptide, and bacterial identification applications.

Another area where TOF-MS excels is high-mass analysis (e.g., intact protein) because its mass range is nearly unlimited. In MALDI-TOF, for example, it is not unusual to detect proteins with molecular weights exceeding 100,000 Da. TOF is also used with ESI and EI ion sources.

Absence of peak skew is another advantage of TOF-MS when it is used as a chromatographic detector. Peak skew is a distortion of the relative abundances of peaks in different parts of a mass spectrum, and this in turn distorts the shape of chromatographic peaks derived from the mass spectral data. Peak skew is related to interaction between the scanning function of the instrument and the changing concentrations of analytes over the elution profile of a chromatographic peak. TOF-MS instruments are essentially free of this artifact.

Trapping mass spectrometers. These mass spectrometers are based on trapping and holding ions for an extended time in a confined space, with the trapping times varying from a fraction of a second to minutes. The division between scanning and nonscanning instruments has less meaning for ion-trapping instruments than for beam-type instruments. The main practical difference between scanning and nonscanning instruments is related to the peak skew, as discussed in the above section on TOF mass analyzers. In terms of producing skewed mass spectra, trapping devices are more similar to nonscanning instruments, such as TOF, than to scanning instruments. This can be explained by capturing ions in an instant and the mass analysis at leisure. Because the sample is captured in an instant, no skewing of the spectra occurs, regardless of whether the m/z analysis is performed by a scanning procedure or by a nonscanning procedure.

Classes of ion traps include (1) quadrupole ion traps (QITs), which act by applying an RF field to provide ion trapping; (2) linear ion traps, which are closely related to QITs in their operating principles; (3) ion cyclotron resonance (ICR) mass spectrometers, which rely on a combination of magnetic fields and electrostatic fields for trapping; and (4) Orbitrap mass spectrometers, which use a static electrical field and orbital dynamics for trapping.

Quadrupole ion trap. QITs are used primarily as gas chromatography (GC) or HPLC detectors. They are (1) relatively compact, (2) relatively inexpensive, and (3) versatile. QITs are useful for exploratory studies, structural characterization, and identification of unknown components of samples.

Operation of the QIT is based on the same physical principle as the quadrupole mass spectrometer because both types of the devices use RF fields to confine ions. However, the RF field of an ion trap is designed to trap ions in three dimensions rather than to allow the ions to pass through as in a QMF, which confines ions in two dimensions. A diagram of an ion trap mass spectrometer is shown in Fig. 13.11. In QIT ions are trapped and selectively ejected to generate a mass spectrum.

Although QITs and QMFs were first described at approximately the same time, the QMF initially achieved greater popularity as an analytical device, especially for quantitative analysis. Later two major discoveries allowed wider implementation of QIT: First, addition into the trap of low-molecular-weight gas (e.g., helium at 10^{-3} torr) improved mass resolution and lowered detection limits; second, the development of mass-selective ejection, which improved QIT scanning performance. When no DC voltage is applied and low RF voltage is used, ions of all m/z are stored in the QIT field. When the RF voltage is increased, ions of increasing m/z become axially unstable and leave the QIT sequentially according to the m/z . Ions leaving the QIT through the end cap are detected by an electron multiplier. In addition, a lower limit of detection is obtained with QIT when an axial modulation waveform is applied to the end cap electrodes. This oscillating voltage improves the efficiency of ion ejection from the trap and improves mass resolution.

Fig. 13.11 Diagram of a quadrupole ion trap mass analyzer.

In addition to the oscillating voltage mode of operation, the QIT is capable of operation in other modes. For example, the QIT may be operated in a mass-selective storage mode that involves selecting a combination of RF and DC that only allows ions of one m/z to be stored in the QIT.

The ability to apply customized waveforms to the QIT makes ion trap one of the most versatile of mass spectrometers, rivaled only by the ICR mass spectrometer. This is most strongly evident in tandem mass spectrometry (MS/MS) and related techniques, which will be discussed later in this chapter.

The QIT also shares some advantages with TOF-MS. In particular, ion trap mass spectrometry is very sensitive. As stated above, because sampling of the ions is decoupled from scanning, no mass spectral peak skewing is seen in GC-MS and HPLC-MS instruments using QIT. One unique capability of QIT, not available in most other types of mass analyzers, is that multiple-stage MS/MS experiments (MS/MS/MS, or MSⁿ) can be performed in this type of instruments.

Linear ion trap. The linear ion trap is an RF ion trap that is based on a modified linear QMF. Rather than serving as a pass-through device like in a normal linear QMF, in a linear ion trap electrostatic fields are applied to the ends to prevent ions from exiting the device. While trapped, ions are manipulated in the same ways as in a QIT. An advantage of the linear quadrupole trap is that it allows more ions to be stored and consequently has a higher dynamic range than a QIT. Commercial triple quadrupole mass spectrometers are available, in which the third quadrupole is modified so it can function either as a QMF or as a linear trap.

Tandem Mass Spectrometers

Tandem mass spectrometry (MS/MS) has become an important technique in clinical and analytical laboratories. In addition to quantitative analysis, MS/MS instruments are useful for compound identification and structural characterization. When

coupled with chromatographic techniques, well-designed MS/MS assay are characterized by (1) high specificity, (2) low consumable cost, and (3) high sample throughput.

The physical principle of **tandem mass spectrometers** is best understood for beam-type instruments. Two mass spectrometers are arranged sequentially, with a “collision cell” placed between the two mass analyzers. The first analyzer is used to select ions of a particular m/z , called *precursor ions*. The precursor ion is directed into the collision cell, where ions collide with background gas molecules and are fragmented into smaller ions, called **product ions**. The second analyzer acquires the mass spectrum of the product ions.

The key to the high selectivity of MS/MS is that it characterizes compounds by two physical properties: precursor ion mass and product ion mass. Chromatographic separation adds a third dimension of selectivity. Use of these three unique properties allows high-specificity analysis and eliminates most of the interferences, which could be encountered using techniques with less selective detection.

As illustrated in Fig. 13.12, a variety of scan functions are possible with tandem mass spectrometers. A product ion scan involves setting the first mass spectrometer, MS1, to select a given m/z and scanning through the full mass spectrum of product ions. This mode of instrument operation is often used for structural characterization of unknown compounds. In **precursor ion scan** mode, the second mass spectrometer (MS2) is set to select a specific product ion, and MS1 is scanned through the spectrum. Peaks in the precursor ion scan are indicative of parent ions producing a specific product ion—a capability that is often used to analyze for specific classes of compounds. A **constant neutral loss** scan consists of scanning both mass spectrometers synchronously, with a constant offset between the two mass analyzers. This scan function is selective for ions that lose a neutral fragment of a specific mass corresponding to the constant offset between the two mass spectrometers. A multiple reaction monitoring (MRM) scan is not actually a scan function but is rather a method of cycling through a list of precursor/product ion pairs.

Fig. 13.12 Scan modes in triple quadrupole mass spectrometry (MS/MS). (A) Shows single reaction monitoring (SRM). The first mass analyzer (MS1) is fixed to monitor a single m/z , and the second mass analyzer (MS2) is fixed to monitor a single m/z . In cases when multiple mass transitions are monitored, this scan type is named “multiple reaction monitoring”. (B) Shows product ion scan mode. MS1 is fixed to monitor a single m/z , and MS2 scans through a range of m/z . (C) Shows precursor ion scan mode. MS2 is fixed to monitor a single m/z , and MS1 is scanned through a range of m/z values.

As with single-stage mass spectrometers, tandem mass spectrometers are categorized as beam-type and trapping instruments. The most popular beam-type instrument is the triple quadrupole. In this instrument, the first quadrupole (Q1) functions as MS1, and the third quadrupole (Q3) functions as MS2. Between these two quadrupoles is another quadrupole, Q2, which functions as the collision cell rather than as a QMF.

So-called hybrid mass spectrometers include a combination of two different types of mass spectrometers in a tandem arrangement. One popular type of instrument is the combination of a quadrupole for MS1 and a TOF for MS2. These instruments are mainly used in proteomics and metabolomics research.

POINTS TO REMEMBER

Multiple reaction monitoring (MRM) is a type of mass spectral acquisition in triple quadrupole mass spectrometers that involves cycling through a list of precursor/product ion pairs. With MRM acquisition, both mass analyzers MS1 and MS2 are set in a static mode, whereby only precursor ions specific for the targeted compounds and the internal standards are passed through MS1. These preselected precursor ions are then fragmented in the collision cell, and the fragment ions derived from the compounds of interest are passed by MS2 to the detector.

In triple quadrupole mass spectrometers the first quadrupole (Q1) functions as the first mass analyzer, and the third quadrupole (Q3) functions as the second mass analyzer. Between these two mass analyzers is quadrupole Q2, which functions as the collision cell.

Detectors

With the exception of Fourier-transform ICR MS and Orbitrap type instruments, nearly all mass spectrometers use electron multipliers for ion detection. Three main types of electron multipliers are (1) discrete dynode multipliers; (2) continuous dynode electron multipliers, also known as *channel electron multipliers*; and (3) microchannel plate electron multipliers. Although they are different in design, the principle of operation of all three is based on a multiplication process that is repeated through a chain of dynodes. Most designs of electron multipliers have 12 to 24 discrete dynodes. Both channel electron multipliers and continuous dynode electron multipliers use a continuous semiconducting layer. The multiplication process typically produces a gain of 10^4 to 10^8 , where the generation of one electron at the first dynode produces a pulse of 10^4 to 10^8 electrons at the end of the cascade. The duration of the pulse is typically less than 10 nanoseconds.

Another type of detector used in mass spectrometers is the Faraday cup. This detector collects the ion current directly without going through a multiplication step. The Faraday cup (commonly used with ICP-MS instruments) is used when the ion abundance is so high that it would saturate the output of an electron multiplier.

Data Acquisition and Data Analysis Software

The signal produced by an instrument is digitized, and the digital signal is recorded and processed by computers. Modern MS instruments generate immense quantities of raw data, requiring high computing power. For example, in toxicology laboratories, one important function of the data analysis is library searching, which assists in compound identification. Several commercial libraries are available, including (1) Wiley Registry of Mass Spectral Data (<http://www.wiley.com/WileyCDA/WileyTitle/productCd-1119284228.html>; accessed on October 18, 2017), (2) the US National Institute of Standards and Technology (NIST) Mass Spectral Database (<http://www.nist.gov/srd/nist1a.cfm/>; accessed on October 18, 2017), and the (3) Pfleger, Maurer, Weber drug libraries. In addition, many laboratories generate custom libraries. Important factors in the utility of such libraries include (1) the quality of available spectra, (2) the search algorithm, and (3) the number of entries in the library. Several library search algorithms are available; the most popular are probability-based matching and the dot product matching approaches. All approaches allow assessment of match quality between the observed spectra and the library spectra.

The computer and software are used for (1) controlling the instrument and data acquisition, (2) signal processing, (3) quantitative calibration, (4) calculation of concentrations in quantitative analysis, (5) database searches, and (6) generating reports.

CLINICAL APPLICATIONS

Mass spectrometers coupled with gas and liquid chromatographs (GC-MS and LC-MS) are versatile analytical instruments that allow development of methods of high specificity, high sensitivity, and high throughput analysis of complex samples.

Gas Chromatography-Mass Spectrometry

Gas chromatography-mass spectrometry (GC-MS) has been used for decades in the analysis of biological samples. For example, it is used by the NIST as the definitive method of qualifying standard reference materials and assigning certified values of many clinically relevant analytes. One of the most common applications of GC-MS is in drug testing for clinical or forensic purposes. Because many drugs have relatively low molecular weight and are sufficiently volatile, they are suitable for analysis by GC. EI with full-scan mass acquisition is a widely used approach for comprehensive drug screening. Identification of unknown compounds is achieved by comparison of the acquired mass spectra with entries in a mass spectral library. In addition to identification of unknown constituents in the samples, mass spectrometry based techniques are the standard methodology for confirming presence of drugs in samples presumptively found to be positive by immunochemical analyses.

Some examples of the clinical use of GC-MS based methods beyond drug testing are in the quantitative analysis of (1) xenobiotic compounds, (2) steroids, (3) pesticides, (4) pollutants, and (5) inborn errors of metabolism.

An important limitation of GC-MS is the requirement that compounds be sufficiently volatile to allow transfer from the solid or liquid phase to the gas phase, and transfer from the chromatographic column to mass spectrometer. Considering that volatility is required in order for a compound to be amenable to GC analysis, many biological compounds need to be derivatized before they can be analyzed using GC-MS.

Derivatization is a technique that transforms a chemical compound into a different compound of similar, though not identical, chemical structure. Derivatization involves the reaction of chemically active functional groups within the targeted molecule and results in a product that may have improved volatility and stability at elevated temperatures, different boiling and melting temperatures, and more favorable fragmentation patterns during mass analysis. The resulting new chemical and physical properties can be beneficial for making compounds amenable to GC-MS analysis, and may enhance sensitivity and specificity.

Liquid Chromatography-Mass Spectrometry

Compared with gas chromatographs, it is more difficult to interface liquid chromatographs with mass spectrometers because the mobile phase is a liquid rather than a gas. The necessity to evaporate liquids often causes problems for the vacuum pumping system of the mass spectrometer. As discussed above, several interface techniques for coupling liquid chromatographs to mass spectrometers now allow HPLC-MS and HPLC-MS/MS to be successfully applied to a wide variety of applications. In theory, as long as a compound is dissolved in a liquid and can be transferred in a gas phase and ionized, it can be introduced into an MS system.

LC-MS/MS methods are widely used in the areas of (1) newborn screening for metabolic disorders, (2) endocrinology and metabolism, (3) toxicological drug screening and confirmation, (4) therapeutic drug monitoring, (5) measurement of cancer biomarkers, and (6) analysis of protein and peptide biomarkers. The majority of current methods for targeted analysis use MRM acquisition, using mass transitions specific to the analyte of interest (Fig. 13.12A).

An important area in which tandem mass spectrometry is used clinically is newborn screening and confirmation of genetic and metabolic disorders. The ability to analyze multiple compounds in a single analysis makes this technique a highly efficient tool for screening purposes. For example, electrospray tandem MS is the most commonly used methodology for analysis of acylcarnitines and amino acids, which are used to screen for disorders of: fatty acid oxidation, organic acid metabolism, the urea cycle, and enzymes in the steroid pathway.

One difficulty in measuring acylcarnitines and amino acids relates to the different sensitivities required to measure the different analytes. To address this issue, a butyl ester derivatization of carboxyl groups can be used to make the molecules more ionizable in positive ion mode, thus yielding more uniform ionization efficiency and sensitivity. Typical amino acid analysis by MS/MS includes esterification to form butyl esters of amino acids, followed by

LC-MS/MS analysis using collision-induced dissociation, resulting in the loss by most of the derivatized amino acids of a neutral fragment, butyl formate (m/z 102 Da) to enable sensitive analysis. The method uses a neutral loss scan of m/z 102 Da to selectively detect amino acids. The same derivatization strategy based on formation of butyl derivatives can be used for analysis of acylcarnitines, with detection (using precursor ion scan mode) of the molecules resulting in a loss of the m/z 85 Da. Because of rapid analysis, these methods are routinely used for screening of large number of samples.

A large number of quantitative LC-MS and LC-MS/MS assays have been developed and introduced for routine use to measure clinically relevant compounds. In addition to toxicology-related LC-MS applications, quantitative analysis of many endogenous compounds has been achieved, including (1) sex hormones, (2) adrenal steroids, (3) biogenic amines, (4) vitamin D metabolites [25(OH)-vitamin D and 1,25(OH)₂-vitamin D], (5) bile acids, (6) methylmalonic acid, (7) homocysteine, and (8) thyroid hormones.

For quantification of targeted compounds, the most effective approach is MRM analysis (Fig. 13.12). With MRM acquisition both mass analyzers, MS1 and MS2 are set in a static mode, whereby only precursor ions specific for the targeted compounds and the internal standards are passed through MS1. These preselected precursor ions are then fragmented in the collision cell, and the fragment ions derived from the compounds of interest are passed by MS2 to the detector. Because only molecule-specific ions are transmitted through MS1 and typically two molecule specific fragment ions are transmitted through MS2, the MRM approach allows much greater specificity of analyses, as well as lower limits of quantification.

Matrix-Assisted Laser Desorption/Ionization–Time of Flight Mass Spectrometry

MALDI is typically coupled with TOF mass analyzers (Fig. 13.13). During the last few years, identification of microorganisms using MALDI-TOF has become widely accepted for routine use in clinical laboratories. Identification of the microorganisms by MALDI-TOF is performed by analysis of extracts of cultured microorganisms. The fact that different bacteria express unique mixture of proteins and peptides serves as the basis of bacteria identification. When culture samples are analyzed using MALDI-TOF, the bacteria specific mass spectra are observed in the mass range of m/z 2000 to 20,000 Da, allowing the use of mass spectral libraries with fingerprints of the peaks corresponding to the bacteria-specific proteins and peptides. Some of the disadvantages of the technique are related to the lack of information on the identity of most of the observed mass spectral peaks, inability to distinguish some strains of the bacteria, and that the mass spectral libraries are typically specific to the method of sample preparation.

Some limitations of MALDI inherent of the ionization process are (1) MALDI cannot be directly interfaced with

Fig. 13.13 An example of a matrix-assisted laser desorption/ionization–time of flight spectrum showing peptides generated in a tryptic digest of a spot from a two-dimensional sodium dodecyl sulfate-polyacrylamide gel.

online separations (e.g., HPLC, capillary electrophoresis), (2) there is a high background noise in MALDI mass spectra, and (3) poor reproducibility among individual scans. Because of the above, MALDI-TOF mass spectrometry is predominantly a qualitative technique. Progress has been made toward MALDI-TOF use for quantitative analysis; however, such applications often require off-line sample preparation and fractionation prior to the instrumental analysis.

Inductively Coupled Plasma Mass Spectrometry

In clinical laboratories, ICP-MS is used for quantification of trace elements in whole blood, urine, plasma, serum, and tissue biopsy samples. Clinical reasons for analyzing biological samples for trace elements include screening and confirmation of suspected heavy metal poisoning, and diagnosing/monitoring patients with metabolic disorders (e.g., Wilson disease). In some cases, toxicity depends on the presence the metal within organic or inorganic molecules. In these cases it could be important to determine concentration of the element in specific molecules, rather than the total concentration of the element in the sample. These applications use sample fractionation with HPLC or capillary electrophoresis to separate various metal-containing molecules before sample introduction in an ICP-MS instrument.

Proteomics and Metabolomics

In the mid-1990s MS came to the forefront of analytical techniques used to study proteins, and the term *proteomics* was coined. Currently MS is routinely used to accomplish many tasks in proteomics. Traditionally proteomics referred to the identification and quantification of proteins and their posttranslational modifications. A common approach to identify proteins is known as the bottom-up analysis, whereby proteins are enriched and then digested. The resulting digests are then analyzed, and the detected peptides are matched to the theoretical digests using mass spectral databases. Partial sequencing of intact proteins may be achieved without prior digestion of proteins

to peptides using top-down techniques, or using partially digested proteins using a middle-down approach. Approaches used for protein top-down characterization include extraction of the proteins from samples, followed by fractionation and analysis of the samples using high-resolution MS/MS with collision induced dissociation, higher energy collision dissociation (HCD), electron capture dissociation (ECD), or electron-transfer dissociation (ETD) fragmentation. The main benefits of the top-down and middle-down analyses are in the ability to detect proteins containing posttranslational modifications and sequence variants.

Most often the term *proteomics* is used in the context of biomarker discovery. In clinical diagnostic testing, it also includes qualitative and quantitative analysis of known protein and peptide biomarkers. One of methods recently introduced in routine testing is quantitative analysis of thyroglobulin (Tg), a marker for the recurrence of thyroid cancer. Measurement of Tg is commonly used for the follow-up of patients treated for differentiated thyroid carcinoma. Because thyroid tissue is the only source of Tg, after total thyroidectomy and radioactive ablation, serum concentrations of Tg should decrease to very low or undetectable concentrations. A rise in the serum concentration of Tg is indicative of cancer recurrence. The presence of endogenous anti-Tg autoantibodies (Tg-AAb) can mask the epitopes used by reagent antibodies in immunoassays for Tg, and this may lead to false negative results. The LC-MS/MS based methods for measurement of Tg overcome this interference of Tg-AAb. The published methods use enzymatic digestion of proteins present in samples. During the digestion, Tg and Tg-AAb get digested, allowing accurate measurement of Tg based on the concentration of Tg-specific peptides present in the digested samples. Currently LC-MS/MS methods for thyroglobulin are offered in several commercial laboratories; the method provides an important tool for physicians monitoring patients for the recurrence of thyroid cancer. Introduction of these methods for the measurement of Tg in clinical practice is one example of the application of mass spectrometry for routine quantitative measurement of proteins. LC-MS/MS methods have also been used for hemoglobinopathies, insulin analogs, quantitative measurement of insulin-like growth factor, parathyroid hormone (PTH), parathyroid hormone related protein (PTHrP), and other clinically relevant protein biomarkers. Another area where MS plays an important role is the field of *metabolomics*. This scientific area investigates and characterizes intermediates and products of metabolism that are present in biological fluids under various conditions. Some particular areas of interest in metabolomics include (1) normal homeostasis, (2) disease states, (3) stress, (4) dietary modification, (5) treatment protocols, and (6) aging. In a fashion similar to a mass spectrum providing a fingerprint signature for a specific molecule, patterns of compounds identified in metabolomic studies may provide a fingerprint signature for different physiologic states.

REVIEW QUESTIONS

- Which of the following types of mass spectrometers involve a single path for ions through the instrument, followed by the ions striking a detector where they are destructively detected?
 - Trapping type
 - Beam type
 - Mass-selective ejection type
 - Ion-cyclotron resonance type
- In mass spectrometry, the sum of all ions produced displayed as a function of time represents:
 - product ion.
 - extracted ion profile.
 - mass spectrum.
 - total ion chromatogram.
- Which type of ionization technique uses an electron beam to ionize the reagent gas and produce a reactive species as a result of ion-molecule reactions?
 - Electron
 - Chemical
 - Electrospray
 - Inductively coupled plasma
- Inductively coupled plasma mass spectrometry is typically used for:
 - determination of trace elements.
 - identification of a protein.
 - drug identification.
 - isotopic labeling of molecules.
- The ionization technique most commonly used in mass analyzers coupled with gas chromatography is:
 - electrospray ionization.
 - chemical ionization.
 - matrix-assisted laser desorption/ionization.
 - electron ionization.
- The mass spectrometer most commonly used for quantitative analysis is the:
 - quadrupole mass spectrometer.
 - time-of-flight instrument.
 - magnetic sector mass spectrometer.
 - linear ion trap mass spectrometer.

Enzyme and Rate Analyses

Renze Bais, Mauro Panteghini

OBJECTIVES

1. Understand how enzymes are used in diagnosis and monitoring disease conditions.
2. Delineate how enzymes are classified in the Enzyme Commission (EC) system and give an example.
3. Give examples of primary, secondary, tertiary, and quaternary structures of enzymes.
4. Understand the importance of the relationship of structure to enzyme function.
5. Give an example of how enzymes carry out their reactions at the active site.
6. Write an equation for the formation of an enzyme-substrate complex.
7. Describe how enzymatic reactions are influenced by changes in:
 - a. Enzyme concentration
 - b. Substrate concentration
 - c. Ionic concentration
 - e. Temperature
 - f. Inhibitors and activators
8. Give an example of an enzyme assay and describe how it works.
9. Write an equation that delineates how the velocity of an enzyme reaction depends on substrate concentration.
10. Describe three different kinds of enzyme inhibition.
11. Understand the use of enzymes as analytical reagents.

KEY WORDS AND DEFINITIONS

Activator Small molecule or ion that increases the rate of an enzyme-catalyzed reaction by promoting formation of the most active state of the enzyme, substrate, or other reactant.

Active center/active site That part of an enzyme formed by the tertiary structure at which the noncovalent binding of substrate occurs to form the intermediate enzyme-substrate complex.

Catalyst A substance that modifies and increases the rate of a chemical reaction without being permanently changed or consumed; an enzyme is a protein catalyst of biological origin.

Clinical enzymology The branch of medical science that deals with the biochemical nature and activity of enzymes of clinical relevance.

Coenzyme A small molecule (some contain structures derived from vitamins) that is required for some enzyme-catalyzed reactions to occur. Coenzymes are temporarily or permanently bound to the enzyme.

Enzyme A protein with catalytic properties.

First-order kinetics A phase in an enzymatic reaction where substrate concentration is limiting and the reaction rate is proportional to the concentration of substrate.

Inhibitor A substance that reduces the rate of an enzymatic reaction and is classified as reversible or irreversible.

International unit The quantity of enzyme that catalyzes one micromole of substrate per minute.

Isoenzyme A form of an enzyme that originates at the level of the gene that encodes the structure of the enzyme protein and is distinguished by certain physical properties.

Isoform A form of an enzyme that is modified by posttranslational processing.

Katal The quantity of an enzyme that catalyzes a reaction rate of one mole of substrate per second.

Lineweaver-Burk plot A plot of the reciprocal of the velocity of an enzyme catalyzed reaction (ordinate; y-axis) against the reciprocal of the substrate concentration (abscissa; x-axis).

Michaelis-Menten constant (K_m) A constant for a given enzyme acting under given conditions; the experimentally determined substrate concentration at which the enzymatic reaction velocity equals one-half of the maximum velocity of the enzymatic reaction.

Product The substance produced by an enzyme catalyzed conversion of a substrate.

Substrate A reactant in an enzyme-catalyzed reaction that binds to the active center of an enzyme.

Zero-order kinetics A phase in an enzymatic reaction when the substrate concentration is saturating and the reaction rate is maximal; the reaction rate depends only on the enzyme concentration and is independent of substrate concentration.

Enzymes are biological catalysts that can be used in the monitoring and diagnosis of disease. Enzymes have remarkable properties that make them sensitive indicators of pathologic change. Metabolism can be regarded as an integrated series of enzymatic reactions, and some diseases as a derangement of the physiologic pattern of metabolism. Many enzymes exist in multiple forms and differences in their properties help in differentiating them and understanding organ-specific pathophysiology. Genetically determined variations in enzyme structure between individuals are used to account for such characteristics as differences in sensitivity to drugs and differences in metabolism, which manifest themselves as hereditary metabolic diseases.

ENZYME NOMENCLATURE

Historically, individual enzymes were identified using the name of the **substrate** or group on which they act and then adding the suffix *-ase*. For example, the enzyme hydrolyzing urea was *urease*. Later, the type of reaction involved was identified, as in carbonic anhydrase, D-amino acid oxidase, and succinate dehydrogenase. In addition, some enzymes were given empirical names such as trypsin, diastase, ptyalin, pepsin, and emulsin.

Because this combination of trivial common names and semisystematic names was found to be inadequate, in 1955 the International Union of Biochemistry (IUB) appointed an Enzyme Commission (EC) to study the problem of enzyme nomenclature. Its subsequent recommendations, with periodic updating, provide a rational and practical basis for

identifying all enzymes now known and enzymes that will be discovered in the future.

With the IUB system, a systematic and trivial name is provided for each enzyme. The systematic name describes the nature of the reaction catalyzed and is associated with a unique numeric code. The trivial or practical name, which may be identical to the systematic name but is often a simplification of it, is suitable for everyday use. The unique numeric designation for each enzyme consists of four numbers, separated by periods (e.g., 2.2.8.11), and is prefixed by the letters *EC*, denoting *Enzyme Commission*. The first number defines the class to which the enzyme belongs. All enzymes are assigned to one of six classes, characterized by the type of reaction they catalyze: (1) oxidoreductases, (2) transferases, (3) hydrolases, (4) lyases, (5) isomerases, and (6) ligases. The next two numbers indicate the subclass and the sub-subclass to which the enzyme is assigned. For example, these may differentiate the amino-transferring subclass from the phosphate-transferring subclass, or the sub-subclass accepting ethanol from those accepting acyl groups. The last number is the specific serial number given to each enzyme within its sub-subclass.

Table 14.1 lists selected enzymes of clinical interest, identified by trivial, abbreviated, and systematic names and by their code numbers.

Although not recommended by the EC, it is a common and convenient practice to use capital letter abbreviations for the names of certain enzymes, such as ALT for alanine aminotransferase, AST for aspartate aminotransferase, LD for lactate dehydrogenase, and CK for creatine kinase (see Table 14.1).

TABLE 14.1 Enzyme Commission Numbers, Systematic and Trivial Names, and Frequently Adopted Abbreviations of Enzymes of Major Clinical Importance

EC Number	Systematic Name	Trivial Name	Abbreviation
1.1.1.27	L-Lactate: NAD ⁺ oxidoreductase	Lactate dehydrogenase	LD
1.4.1.3	L-Glutamate: NAD(P) ⁺ oxidoreductase (deaminating)	Glutamate dehydrogenase	GLD
2.3.2.2	(γ -Glutamyl)-peptide: amino acid γ -glutamyltransferase	γ -Glutamyltransferase	GGT
2.6.1.1	L-Aspartate: 2-oxoglutarate aminotransferase	Aspartate aminotransferase (transaminase)	AST
2.6.1.2	L-Alanine: 2-oxoglutarate aminotransferase	Alanine aminotransferase (transaminase)	ALT
2.7.3.2	ATP: creatine <i>N</i> -phosphotransferase	Creatine kinase	CK
3.1.1.3	Triacylglycerol acylhydrolase	Lipase	LPS
3.1.1.7	Acetylcholine acetylhydrolase	Acetylcholinesterase, true cholinesterase, choline esterase I	—
3.1.1.8	Acetylcholine acylhydrolase	Pseudocholinesterase, butyryl cholinesterase, choline esterase II (serum cholinesterase)	CHE
3.1.3.1	Orthophosphoric-monoester phosphohydrolase (alkaline optimum)	Alkaline phosphatase	ALP
3.1.3.2	Orthophosphoric-monoester phosphohydrolase (acid optimum)	Acid phosphatase	ACP
3.1.3.5	5'-Ribonucleotide phosphohydrolase	5'-Nucleotidase	NTP
3.2.1.1	1,4- α -D-Glucan glucanohydrolase	Amylase	AMY
3.4.21.4		Trypsin	TRY
4.1.2.13	D-Fructose-1,6-bisphosphate D-glyceraldehyde-3-phosphate-lyase	Aldolase	ALD

EC, Enzyme Commission; NAD, nicotinamide adenine dinucleotide; NAD(P), NAD phosphate.

ENZYMES AS PROTEINS

Enzymes are proteins and thus possess the primary, secondary, and tertiary structural characteristics of proteins (see [Chapter 18](#)). Many enzymes also exhibit quaternary structure. The *primary* structure, the linear sequence of amino acids linked through their α -carboxyl and α -amino groups by peptide bonds, is specific for each type of enzyme molecule. Each polypeptide chain is coiled into three-dimensional (3D) secondary and tertiary structures. Secondary structure refers to the conformation of limited segments of the polypeptide chain, namely α -helices, β -pleated sheets, random coils, and β -turns. The combination of secondary structural elements and amino acid side chain interactions that define the 3D structure of the folded protein is referred to as its tertiary structure. In many cases, biological activity, such as the catalytic activity of enzymes, requires two or more folded polypeptide chains (subunits) to associate to form a functional molecule. The specific combination of these subunits defines the quaternary structure. The subunits may be multiples of the same polypeptide chain (e.g., the MM isoenzyme of CK, the H₄ isoenzyme of LD), or they may be combinations of distinct polypeptides (e.g., the MB isoenzyme of CK).

No feature of primary structure is common to all enzyme molecules. However, considerable homologies of amino acid sequences are found between enzymes that appear to share a common evolutionary origin, such as the proteases trypsin and chymotrypsin. Similarities of sequence are even more marked among the members of a family of isoenzymes. The amino acid sequence in the immediate neighborhood of the **active center** of the enzyme (discussed later) is often similar in enzymes with related function (e.g., the *serine proteases* are so called because they all have this amino acid in the active center).

Enzyme molecules differ in the proportion of secondary structures—such as α -helices—that they contain, although no enzyme molecule studied thus far approaches the large proportion of α -helices found in myoglobin and hemoglobin. The tertiary structures of different types of enzyme molecules are as individually characteristic as their primary structures; nevertheless, some common features exist. Enzyme molecules are roughly globular in overall shape, with a preponderance of polar amino acid side chains on the outside of the molecule and nonpolar side chains in the interior. The ionizable residues in contact with the surrounding medium are responsible for many of the properties of the enzyme molecules in solution, such as their migration in an electric field and their solubility. Covalent disulfide bridges may link different parts of the polypeptide chains in some enzyme molecules, but the 3D structure is mainly stabilized by the large number of hydrophobic interactions formed between the nonpolar side chains in the interior of the molecule.

The application of physical methods, such as x-ray crystallography and multidimensional nuclear magnetic resonance, has provided structural insights from which enzyme mechanisms have been proposed. Furthermore, the tools of molecular biology, such as molecular cloning, have enabled the

purification and characterization of enzymes that previously were available only in minute amounts. Molecular biology also enables the manipulation of the amino acid sequence of enzymes. Site-directed mutagenesis (substituting one amino acid residue for another) and deletion mutagenesis (eliminating sections of the primary structure) have enabled the identification of chemical groups that participate in ligand binding and specific chemical steps during catalysis. The biological activity of a protein molecule depends generally on the integrity of its structure, and any disruption of its structure will likely be accompanied by a loss of activity, a process known as *denaturation*. If the process of denaturation is minimal, it may be reversed with the recovery of enzyme activity on removal of the denaturing agent. However, prolonged or severe denaturing conditions result in an irreversible loss of activity. Denaturing conditions include increased temperatures, extremes of pH, and exposure to certain chemicals. Heat inactivation of most enzymes takes place at an appreciable rate at room temperature, and in most cases becomes very fast above 60°C. However, certain enzymes, most notably some polymerases, can retain activity at temperatures as high as 95°C. This property has been exploited in the polymerase chain reaction (see [Chapter 48](#)). Extremes of pH also cause unfolding of enzymes and, with few exceptions, should be avoided when enzyme samples are preserved. Addition of chemicals, such as urea and detergents, disrupts hydrogen bonding and hydrophobic interactions, also resulting in enzyme inactivation.

SPECIFICITY AND THE ACTIVE CENTER

With the exception of enzymes such as proteases, nucleases, and amylases, which act on macromolecular substrates, enzyme molecules are considerably larger than their substrate molecules. Consideration of the structure of an enzyme's active site and its substrate(s) in their ground and transition states is necessary to understand the rate enhancement and specificity of chemical reactions catalyzed by an enzyme. The active site of an enzyme will vary among enzymes, but in general, the following statements hold:

1. The active site of an enzyme is relatively small compared with the total size of the enzyme molecule and may involve less than 5% of its amino acids.
2. The active sites of enzymes are 3D structures that are formed as a result of the overall tertiary structure of the protein. This results in the amino acids and cofactors in the active site of an enzyme being spatially structured in an exact, 3D relationship with respect to one another and to the structure of the substrate molecule.
3. Typically, the binding of substrate molecules to the active site of an enzyme is noncovalent, and is stabilized by hydrogen bonding, electrostatic, hydrophobic, and van der Waals interactions.
4. Active sites of enzymes typically occur in clefts and crevices in the protein's tertiary structure.

The specificity of substrate binding is a function of the exact spatial arrangement of atoms in the enzyme active site that complements the structure of the substrate molecule.

ISOENZYMES AND OTHER MULTIPLE FORMS OF ENZYMES

Isoenzymes are enzymes that can catalyze the same reaction, but that differ in some aspect of their structure. They may occur within a single organ or even within a single type of cell. The forms can be distinguished on the basis of differences in various properties, such as electrophoretic mobility, immunological reactivity, and resistance to chemical or thermal inactivation. They often have significant quantifiable differences in catalytic properties, but all forms of a particular enzyme retain the ability to catalyze its characteristic reaction.

The existence of multiple forms of enzymes in human tissue has important implications in the study of human disease. The presence in different organs of isoenzymes with distinctive properties helps in understanding organ-specific patterns of metabolism. Genetically determined variations in enzyme structure among individuals account for such characteristics as differences in sensitivity to drugs and differences in metabolism, which manifest themselves as hereditary metabolic diseases. For diagnostic enzymology, the existence of multiple forms of enzymes, whether the result of genetic or nongenetic causes, provides opportunities to increase the diagnostic specificity and sensitivity of enzyme assays in body fluid samples.

Similar to other proteins, enzymes usually elicit the production of antibodies when they are injected into animals of a species other than those in which they originate. Even small structural differences among closely similar molecules, such as the members of a family of isoenzymes, are often sufficient to render them antigenically distinct, allowing antibodies to be produced specific to a single isoenzyme. The availability of immunochemical methods has been particularly important in the analysis of isoenzyme mixtures with many commercial immunoassays using monoclonal antibodies to increase specificity.

Genetic Origins of Enzyme Variants

True isoenzymes result from the existence of more than one gene coding for the structure of the enzyme protein. Many human enzymes (more than one-third) are known to be determined by more than one structural gene. Similar but distinct genes have undergone differential modifications during the course of evolution, so that the enzyme proteins coded by them no longer have identical structures, although they can catalyze the same reaction; in other words, they are isoenzymes.

The multiple genes that determine a particular group of isoenzymes are not necessarily closely linked on one chromosome. For example, the structural genes that code for human salivary and pancreatic amylases both are located on chromosome 1, whereas the genes that code for cytoplasmic and mitochondrial malate dehydrogenase are on chromosomes 2 and 7, respectively. Among the enzymes of clinical importance that exist as isoenzymes because of the presence of multiple-gene loci are LD, CK, α -amylase, and some forms of alkaline phosphatase (ALP).

An enzyme can exist in molecular forms that differ from one individual to another because of the existence of alternative alleles that are inherited according to Mendelian laws. These alleles give rise to gene **products**, enzymes, with the same function. Isoenzymes that result from the existence of different alleles are termed *allozymes*. Many human genes have allelic variation and the probability that individuals will differ in their isoenzyme patterns is high.

The number of allelic variants and the frequency with which particular variants occur within the population vary considerably across enzymes. For example, mutations at either of the two principal loci that determine human LD are extremely rare, but a high incidence of mutant alleles occurs at the single locus that determines the structure of placental ALP. More than 400 mutations in the glucose-6-phosphate dehydrogenase gene have now been identified on the X chromosome. When isoenzymes, because of variation at a single locus, occur with appreciable frequency in a human population, the population is said to be *polymorphic* with respect to the isoenzymes in question.

Another category of multiple molecular forms can arise when enzymes are oligomeric, and possess quaternary structure. The association of different subunits in various combinations gives rise to a range of active enzyme molecules. When the subunits are derived from different structural genes—multiple genes or multiple alleles—the hybrid molecules so formed are called *hybrid isoenzymes*. The ability to form hybrid isoenzymes is evidence of considerable structural similarities among the different subunits. Hybrid isoenzymes can be formed in vitro, but they are also formed in vivo when different types of constituent subunits are present in the same subcellular compartment.

The number of different hybrid isoenzymes that can form from two nonidentical protomers depends on the number of subunits in the complete enzyme molecule. For a dimeric enzyme, one mixed dimer (hybrid isoenzyme) can be formed. If the enzyme is a tetramer, three heteropolymeric isoenzymes may be formed (Fig. 14.1). Examples of hybrid isoenzymes include the mixed MB dimer of CK and the three hybrid isoenzymes, LD-2, LD-3, and LD-4 of LD.

Nongenetic Causes of Multiple Forms of Enzymes

Posttranslational modifications of enzyme molecules give rise to multiple forms known as **isoforms** (Fig. 14.2). For example, removal of amide groups accounts for some of the heterogeneity of amylase and carbonic anhydrase (each of these enzymes also exists as a true isoenzyme). Modification also can take place as a result of extraction procedures. Many erythrocyte enzymes, including adenosine deaminase, acid phosphatase, and some forms of phosphoglucomutase, contain sulfhydryl groups that are susceptible to oxidation. In hemolysates, oxidation may be brought about by the action of oxidized glutathione, although in intact cells, this compound is present in its reduced form.

Serum isoforms of CK are formed as part of the normal clearance process of the cell. Human myocardial and skeletal muscle tissues have the CK-MM and CK-MB isoenzymes, which

Fig. 14.1 Diagram showing the origin of isoenzymes, assuming the existence of two distinct genes. When the active enzymes are polymers containing more than one subunit, hybrid isoenzymes consisting of mixtures of different subunits may be formed. One such isoenzyme can be formed in the case of a dimeric enzyme, such as creatine kinase and three if the enzyme is a tetramer (e.g., lactate dehydrogenase). In both cases, two homopolymeric isoenzymes can also exist. (From Moss, D. W. [1979]. *Isoenzyme analysis*. London: The Chemical Society. Reproduced by permission of The Royal Society of Chemistry.)

are modified on release into the circulation by removal of the C-terminal amino acid lysine from the M subunits by the action of carboxypeptidase.

Modifications of enzyme molecules also may include non-protein components that lead to molecular heterogeneity. Many enzymes are glycoproteins, and variations in carbohydrate side chains are a common cause of nonhomogeneity. Some carbohydrate moieties, notably *N*-acetylneuraminic acid (sialic acid), are strongly ionized and consequently have a profound effect on some enzyme molecules. For example, removal of terminal sialic acid groups from human liver and/or bone ALP with neuraminidase greatly reduces the electrophoretic heterogeneity of the enzyme.

Aggregation of enzyme molecules with each other or with nonenzymatic proteins may give rise to multiple forms that can be separated by techniques that depend on differences in molecular size. For example, four catalytically active cholinesterase components with molecular weights ranging from approximately 80,000 to 340,000 are found in most sera, with the heaviest component, C_4 , contributing most of the enzyme activity. Other enzyme forms are also occasionally present, but it appears that the principal serum cholinesterase fractions can be attributed to different states of aggregation of a single monomer.

A specific form of interaction between enzymatic and non-enzymatic proteins, such as immunoglobulins, results in the formation of an enzyme-protein complex (macrocomplex). Enzyme-immunoglobulin complexes have been observed involving amylase, LD, CK, ALP, amylase, and other enzymes.

Fig. 14.2 Nongenetic modifications that may give rise to multiple forms of enzymes. (From Moss, D. W. [1982]. *Isoenzymes*. London: Chapman & Hall.)

A single polypeptide chain, in theory, exists in an infinite number of different conformations. However, one specific conformation generally appears to be the most stable for any given sequence of amino acids, and this conformation is assumed by the chain as it is synthesized within the cell. Thus the primary structure of the polypeptide chain also determines its 3D secondary and tertiary structures. It is conceivable that in some cases, several alternative conformations (conformers) of a single chain that are almost equally stable may be present, and therefore these alternative forms may coexist. However, multiple-enzyme forms that demonstrate conformational isomerism have not been shown unequivocally.

Changes in Isoenzyme Distribution During Development and Disease

The patterns of many isoenzymes change during physiologic development in tissues from many species. For example, during the embryonic development of skeletal muscle, the proportions of more cationic isoenzymes—both LD and CK—progressively increase until approximately the sixth month of intrauterine life when the pattern resembles that of differentiated muscle.

The liver also shows characteristic changes in the patterns of several isoenzymes during embryogenesis. In early fetal development, three aldolase isoenzymes—A, B, and C—together with various hybrid tetramers, can be detected in extracts of liver. However, at birth, as in the adult liver, aldolase B is the predominant isoenzyme. Striking changes in the distribution of isoenzymes of alcohol dehydrogenase also occur in human liver during prenatal development.

Changes in isoenzyme patterns during development result from changes in the relative activities of different genes within developing cells of a particular type (e.g., muscle cells). Other alterations in the balance of isoenzymes within the whole organism may derive from changes in the number or activity of cells that contain large amounts of a characteristic isoenzyme. An example of this is the increased number and activity of the osteoblasts, which are responsible for mineralization of the skeleton between the early postnatal period and the beginning of the third decade of life. An excess of ALP from active osteoblasts enters the circulation, where its presence can be recognized by its characteristic properties and where it increases the total serum ALP activity of young individuals to values higher than in skeletally mature adults. An ALP from the liver also contributes to the total activity of this enzyme in the plasma of healthy individuals, and the amount of this form in plasma shows a small, progressive increase with age. The reason for the latter age-dependent change is not known, but it may result from increased synthesis of the enzyme by hepatocytes in response to continuing exposure to inducing factors.

The distributions of isoenzymes of aldolase, LD, and CK in the muscles of patients with progressive muscular dystrophy are similar to those in the early development of fetal muscle. Isoenzyme abnormalities in dystrophic muscle have been interpreted as failure to reach or maintain a normal degree

of differentiation. Isoenzyme patterns seen in regenerating tissues also may show some tendency to approach fetal distributions. This tendency may result from relaxation or modification of control systems in rapidly dividing cells and may account for some of the isoenzyme changes noted (e.g., in muscle in acute polymyositis).

Cancer cells show progressive loss of the structure and metabolism of the healthy cells from which they arise. Therefore the pattern of isoenzymes of mature, differentiated tissue may be lost or modified if normal differentiation is arrested or reversed; and many examples of isoenzyme changes accompanying cancer have been reported. Reemergence of fetal patterns of isoenzyme distribution is a feature of malignant transformation in many tissues. This phenomenon was first studied extensively in the case of LD isoenzymes. Malignant tumors in general show a significant shift in the balance of isoenzymes toward LD-4 and LD-5. The decline in activity of the LD-1 and LD-2 isoenzymes results in patterns that are reminiscent of those occurring in embryonic tissues. Tumors of prostate, cervix, breast, brain, stomach, colon, rectum, bronchus, and lymph nodes are among those that show this transformation. In contrast, comparatively benign gliomas show a relative increase in LD-1 and LD-2. A relative increase in the proportion of LD-4 and LD-5 has been observed in tissue adjacent to malignant tumors (e.g., the colon), although the cells in these regions are morphologically normal.

Differences in Properties Among Multiple Forms of Enzymes

Structural differences among the multiple forms of an enzyme give rise to differences in physicochemical properties, such as electrophoretic mobility, resistance to inactivation, and solubility, or in catalytic characteristics, such as preferential reactions with substrate analogs or natural substrates, or relative susceptibility to inhibitors. Methods of isoenzyme analysis have therefore been designed to investigate a wide range of catalytic and structural properties of enzyme molecules. However, it is usually possible to make only limited deductions about the nature of the underlying structural differences between isoenzymes that are responsible for the dissimilar properties. Equally, the changes in properties that may result from specific structural alterations in enzyme molecules are difficult to predict.

Techniques of molecular biology, such as gene cloning and sequencing, have revolutionized investigation of the primary structures of isoenzymes. Differences in primary structures among isoenzymes, whether derived from multiple genes or from different alleles, are now known to exist in a growing number of cases. Furthermore, many questions have been answered about whether multiple-enzyme forms represent true (genetically determined) isoenzymes or result from post-translational modification.

Isoenzymes caused by the existence of multiple genes usually differ quantitatively in catalytic properties. These differences may be manifested in such characteristics as molecular activity, K_m values for substrate(s), sensitivity to various inhibitors, and relative rates of activity with substrate analogs

(when the specificity of the isoenzymes allows the substrate to be varied), underscoring the biological importance of isoenzymatic variation. In contrast, multiple-enzyme forms that arise by posttranslational modifications such as aggregation usually have similar catalytic properties.

Multigene isoenzymes also usually differ in terms of antigenic specificity, although these differences may be less pronounced among isoenzymes that have emerged relatively recently in evolutionary history and are closely related in structure. Immunologic cross-reaction is not uncommon among multigene isoenzymes. Multiple-enzyme forms caused by posttranslational modification frequently have common antigenic determinants. Isoenzymes derived from different alleles of the same gene (allozymes) are also often antigenically similar, even to the extent that they may cross-react with antisera to the common isoenzyme, despite a mutation having abolished enzyme activity altogether. The capacity for detecting differences among antigenically similar isoenzyme molecules depends on the extent of monoclonal antibody specificity.

Differences in resistance to denaturation (e.g., by heat, concentrated urea solutions, detergents) are commonly found among true isoenzymes, whether these are the products of multiple genes or multiple alleles. Other multiple forms of enzymes often do not differ or differ only slightly in this respect. The most commonly exploited difference among isoenzymes is the difference in net molecular charge that results from the altered amino acid compositions of the molecules; this forms the basis of separation by zone electrophoresis, ion-exchange chromatography, or isoelectric focusing. Separation methods that depend on differences in molecular size, such as gel filtration, do not distinguish among the small size differences that often exist among true isoenzyme molecules but are important in the detection of multiple forms that involve aggregation or association of enzyme molecules with other proteins, such as immunoglobulins.

ENZYMES AS CATALYSTS

A **catalyst** is a substance that modifies and increases the rate of a particular chemical reaction without being consumed or permanently altered. Enzymes are protein catalysts of biological origin. Metabolism is a coordinated series of chemical reactions that occur within a living cell to provide energy and accomplish biosynthesis. The process can be regarded as an integrated series of enzymatic reactions, whereas some diseases can be viewed as a derangement of the normal pattern of metabolism. The remarkable properties of enzymes make them sensitive indicators of pathologic change.

Because of their catalytic activity, enzymes convert an enormous number of substrate molecules into products within a short time. This property is used to measure increased amounts of enzymes in the bloodstream, although the amount of enzyme protein released from damaged cells is small compared with the total quantity of nonenzymatic proteins in blood.

UNITS FOR EXPRESSING ENZYME ACTIVITY

When enzymes are measured by their catalytic activities, the results are expressed as *units of activity*. The unit of activity is defined by the rate at which the reaction proceeds (e.g., the quantity of substrate consumed or product formed in a chosen unit of time). In **clinical enzymology**, enzyme activity is generally reported as units of activity per unit of volume, such as units per 100 mL, per liter of serum, or per 1.0 mL of packed erythrocytes. Because the rate of the reaction depends on experimental parameters, such as pH, type of buffer, temperature, nature of substrate, ionic strength, concentration of activators, and other variables, these parameters must be specified in the definition of the unit.

To standardize how enzyme activities are expressed, the EC proposed that the unit of enzyme activity should be defined as the quantity of enzyme that catalyzes the reaction of 1 μmol of substrate per minute and that this unit should be termed the **international unit** (U). Catalytic concentration is expressed in terms of units per liter (U/L) or kilounits (kU/L), whichever gives the more convenient numeric value. In this chapter, the symbol U is used to denote the international unit. In those instances in which there is some uncertainty about the exact nature of the substrate, or when difficulty is encountered in calculating the number of micromoles reacting (as with macromolecules such as starch, protein, and complex lipids), the unit is expressed in terms of the chemical group or residue produced in the reaction (e.g., $\mu\text{mol}/\text{min}$ glucose or amino acid formed).

Contrary to the previously noted EC recommendation, the International System of Units (SI) recommends that enzyme activity be expressed in moles per second or **katal**s. Enzyme concentration can then be expressed in terms of katal per liter (kat/L). The relationship between the EC and SI measures of enzymatic activity is:

$$\begin{aligned} 1 \text{ SI Unit (katal)} &= 1 \text{ mol/s} = 10^6 \mu\text{mol/s} \\ &= 6 \times 10^7 \mu\text{mol/min} = 6 \times 10^7 \text{ EC Units} \end{aligned}$$

The katal is so large that it is difficult to use and therefore, the EC units of enzyme activity ($\mu\text{mol}/\text{min}$) are commonly employed.

POINTS TO REMEMBER

- Enzymes are biological catalysts that can be used in the monitoring and diagnosis of disease.
- Enzymes are proteins with the ability to accelerate or catalyze chemical reactions.
- The characteristics of the reactions catalyzed by an enzyme depend on the structure of its active site and its relationship to substrates.
- Enzymes exist in multiple forms, isoenzymes, the properties and distribution of which are important in diagnosis.

ENZYME KINETICS

Enzyme-Substrate Complex

Enzymes act through the formation of an enzyme–substrate (ES) complex, in which a molecule of substrate is bound to

Fig. 14.3 Activation energy barrier and reaction course, with and without enzyme catalysis. E_{S_f} is the activation energy for the forward reaction ($S \rightarrow P$) in the absence of a catalyst, and E'_{S_f} is the activation energy in the presence of a catalyst. ΔG_0 is the change in free energy for the reaction.

the active center of the enzyme molecule. The binding process transforms the substrate molecule to its activated state. The energy required for this transformation is provided by the free energy of binding of S to E. Therefore activation takes place without the addition of external energy, so that the energy barrier to the reaction is lowered and the conversion to products is accelerated (Fig. 14.3). The ES complex dissociates to give the reaction products (P) and free enzyme (E):

All reactions catalyzed by enzymes are in theory reversible. However, under the conditions found in the human body *in vivo*, or in the clinical lab *in vitro*, the reaction is usually more rapid in one direction than in the other, so that an equilibrium is reached in which the product of the forward or the backward reaction predominates, sometimes so markedly that the reaction is virtually irreversible.

If the product of the reaction in one direction is removed as it is formed (e.g., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process will be displaced so that the reaction will proceed to completion in that direction. Reaction sequences in which the product of one enzyme-catalyzed reaction becomes the substrate of the next enzyme and so on, often through many stages, are characteristic of biological processes. In the laboratory also, several enzymatic reactions may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain. For example, the activity of CK is usually measured by coupling the adenosine triphosphate (ATP) formed in the CK-catalyzed reaction to the phosphorylation of glucose catalyzed by hexokinase, and then coupling the glucose-6-phosphate product to oxidation by glucose-6-phosphate dehydrogenase, with the formation of a photometrically measurable product, nicotinamide adenine dinucleotide phosphate (NADPH).

When a secondary enzyme-catalyzed reaction, known as an indicator reaction, is used to determine the activity of a different enzyme, the primary reaction must be the rate-limiting step. Reaction conditions must ensure that the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

FACTORS GOVERNING THE RATE OF ENZYME-CATALYZED REACTIONS

Factors that affect the rate of enzyme-catalyzed reactions include enzyme and substrate concentration, pH, temperature, and the presence of inhibitors, activators, **coenzymes**, and prosthetic groups.

Enzyme Concentration

The simplest enzymatically catalyzed reaction for converting substrate S into product P with the intermediate formation of an ES complex is as follows:

where E_f = free enzyme; k_1 = rate constant for the association of the complex; k_1 = rate constant for the dissociation of the complex; ES = enzyme-substrate complex; k_2 = rate constant for breakdown of ES to E_f and P; and P = product.

Michaelis and Menten assumed that equilibrium is attained rapidly among E, S, and ES, with the effect of product formation ($ES \rightarrow P$) on the concentration of ES being negligible. In addition, the formation of product is written as an irreversible process because there is no product in the solution under initial conditions. Therefore the overall rate of the reaction under otherwise constant conditions is proportional to the concentration of the ES complex.

Provided that an excess of free substrate molecules is present, addition of more enzyme molecules to the reaction system increases the concentration of the ES complex and thus the overall rate of reaction. This accounts for the observation that the rate of reaction is generally proportional to the concentration of enzyme present in the system and is the basis for the quantitative determination of enzymes by measurement of reaction rates. Reaction conditions are selected to ensure that the observed reaction rate is proportional to enzyme concentration over as wide a range as possible.

Substrate Concentration

In addition to explaining the dependence of reaction rate on enzyme concentration under conditions in which excess substrate is present, the formation of an ES complex accounts for the hyperbolic relationship between reaction velocity and substrate concentration (Fig. 14.4A).

Single-Substrate Reactions

If the enzyme concentration is fixed and the substrate concentration is varied, the rate of reaction is first order and proportional to substrate concentration when the substrate concentration is low. Under these conditions, only a fraction of the enzyme is associated with substrate, and the rate observed reflects the low concentration of the ES complex. At high substrate concentrations, variation in substrate concentration has no effect on rate, and the reaction is zero order with respect to substrate concentration. Under these conditions, all the enzyme is bound to the substrate and a much higher rate of reaction is obtained. Moreover, because all the enzyme is now present in the form of the complex, no further

Fig. 14.4 (A) Michaelis-Menten curve relating the velocity (rate) of an enzyme-catalyzed reaction to substrate concentration. The value of K_m is given by the substrate concentration at which one-half of the maximum velocity is obtained. (B) Lineweaver-Burk transformation of the curve in (A), with $1/v$ plotted on the ordinate (y-axis), and $1/[S]$ on the abscissa (x-axis). The indicated intercepts permit calculation of $V_{\max}$ and K_m .

increase in complex concentration and no further increment in reaction rate are possible. The maximum possible velocity for the reaction has been reached. The significance of substrate-rate curves was first emphasized by Michaelis and Menten, and such curves are referred to as Michaelis-Menten plots.

Referring again to Eq. 14.2, the overall rate of the reaction (v) is determined by the rate at which product is formed:

$$v = \frac{d[P]}{dt} = k_2 [ES] \quad (14.3)$$

The formation of ES will depend on the rate constant k_1 and the availability of enzyme and substrate. If it is assumed that the system is in a steady state with the ES complex being formed and broken down at the same rate so that overall (ES) is constant, then the steady-state equation is

$$k_1 [E] [S] = k_{-1} [ES] + k_2 [ES] \quad (14.4)$$

This equation can be rearranged to:

$$[ES] = \frac{k_1 [E] [S]}{k_{-1} + k_2} \quad (14.5)$$

when these rate constants are combined into a single term; writing the **Michaelis-Menten constant** (K_m) as:

$$K_m = \frac{k_{-1} + k_2}{k_1} \quad (14.6)$$

and then substituting this into Eq. 14.5 gives:

$$[ES] = \frac{[E] [S]}{K_m} \quad (14.7)$$

Because the total amount of enzyme in the system does not change,

$$[E_t] = [ES] + [E] \quad (14.8)$$

and on substituting Eq. 14.3 into Eq. 14.7 and eliminating [ES] using Eq. 14.8,

$$v = k_2 \times \frac{[E_t] \times [S]}{K_m + [S]} \quad (14.9)$$

For a given amount of enzyme, the maximum reaction velocity ($V_{\max}$) is reached when all of the enzyme is saturated with substrate (i.e., $[ES] = [E_t]$), and therefore $V_{\max} = k_2 \times [E_t]$. Substituting this in Eq. 14.9 gives

$$v = \frac{V_{\max} [S]}{K_m + [S]} \quad (14.10)$$

A plot of v against $[S]$ gives a section of a rectangular hyperbola (see Fig. 14.4A), and this is the shape of the curve that is found experimentally for most enzyme reactions. When $[S] = K_m$, K_m is the substrate concentration at which the reaction proceeds at half of its maximum velocity. In practice, it is now customary to restrict K_m to the experimentally determined substrate concentration at which $v = 0.5 V_{\max}$ and to use the symbol K_s to represent the true ES association constant, where this is known.

Although it is simple to set up an experiment to determine the variation of v with $[S]$, the exact value of $V_{\max}$ is not easily determined from hyperbolic curves. Furthermore, many enzymes deviate from ideal behavior at high substrate concentrations and may even be inhibited by the excess of substrate, so the calculated value of $V_{\max}$ cannot be achieved in practice. In the past, it was common practice to transform the Michaelis-Menten equation (Eq. 14.10) into one of several reciprocal forms (Eqs. 14.11 and 14.12), and either $1/v$ was plotted against $1/[S]$, or $[S]/v$ was plotted against $[S]$.

$$\frac{1}{v} = \left(\frac{K_m}{V_{\max}} \times \frac{1}{[S]} \right) + \frac{1}{V_{\max}} \quad (14.11)$$

$$\frac{[S]}{v} = \left(\frac{1}{V_{\max}} \times [S] \right) + \frac{K_m}{V_{\max}} \quad (14.12)$$

Eq. 14.11, for example, when plotted, results in a **Lineweaver-Burk plot** that gives a straight line with intercepts at $1/V_{\max}$ on the ordinate and $-1/K_m$ on the abscissa. The data for Fig. 14.4A are replotted in Lineweaver-Burk form in Fig. 14.4B.

It is now routine practice to determine kinetic constants such as K_m and $V_{\max}$ using software packages. Free and commercial packages are available; these vary from specialized routines for kinetic simulations or for data fitting, to general mathematical, statistical, or graphical packages.

The value of K_m , is to compare the binding of homologous or related substrates to the same enzyme. Also, if measured against the same substrate under defined conditions, the K_m value can be used to compare the properties of similar enzymes from different sources. Isoenzymes determined by distinct genes typically differ in their K_m (e.g., for the isoenzymes of LD).

When setting up methods of enzyme assay, it is necessary to (1) explore the relationship between reaction velocity and substrate concentration over a wide range, (2) determine K_m , and (3) detect any inhibition at high substrate concentrations. **Zero-order kinetics** is maintained if the substrate is present in large excess (i.e., concentrations at least 10 and preferably 100 times that of the value of K_m). When $[S] = 10 \times K_m$, v is approximately 91% of the theoretical $V_{\max}$. The K_m values for the majority of enzymes are on the order of 10^{-5} to 10^{-3} mol/L; therefore substrate concentrations are usually chosen to be in the range of 0.001 to 0.10 mol/L. On occasion, the optimal concentrations of substrate cannot be used, for example, when the substrate has limited solubility or when the concentration of a given substrate inhibits the activity of another enzyme needed in a coupled reaction system.

Two-Substrate Reactions

Most enzymes catalyze reactions with two or more interacting substrates symbolized by the following equation:

When one of the substrates is water (i.e., when the process is one of hydrolysis), with the reaction taking place in aqueous solution, only a fraction of the total number of water molecules present participates in the reaction. The small change in the concentration of water has no effect on the rate of reaction and these pseudo-one substrate reactions are described by one-substrate kinetics. More generally, the concentrations of both substrates may be variable and both may affect the rate of reaction. Among the bisubstrate reactions important in clinical enzymology are the reactions catalyzed by dehydrogenases, in which the second substrate is a specific coenzyme, such as the oxidized or reduced forms of nicotinamide adenine dinucleotide (NADH), or NADPH, and the amino-group transfers catalyzed by the aminotransferases.

If a bisubstrate reaction proceeds by way of intermediate ES complexes, so that

followed by

and if S_1 and S_2 bind to separate sites on the enzyme molecule, the rate of reaction is given by

$$v = \frac{V_{\max} \times [S_1] [S_2]}{[S_1] [S_2] + [S_2] K_m^1 + [S_1] K_m^2 + K_s^1 K_m^2} \quad (14.16)$$

K_m^1 and K_m^2 are the K_m values for the two substrates, and $[S_1]$ and $[S_2]$ are their concentrations. K_s^1 is the equilibrium constant for the reversible reaction between the enzyme and S_1 . If the equation is rearranged into the double reciprocal form,

$$\frac{1}{v} = \frac{1}{[S_1]} \left(\frac{K_m^1}{V_{\max}} + \frac{K_m^2 K_s^1}{[S_2] V_{\max}} \right) + \frac{1}{V_{\max}} \left(1 + \frac{K_m^2}{[S_2]} \right) \quad (14.17)$$

a plot of $1/v$ against $1/[S_1]$ gives a straight line, but both the slope of the line and its intercept on the ordinate are dependent on $[S_2]$, the concentration of the second substrate. A plot of $1/v$ against $1/[S_2]$ is rectilinear but with the slope and intercept dependent on $[S_1]$.

In some bisubstrate reactions, no ternary complex ES_1S_2 is formed, because the binding of the first substrate is followed by release of the first product before the second substrate is bound and the second product is released. This sequence is described as a *ping-pong bi-bi* type of reaction. This occurs in reactions catalyzed by aminotransferases.

The relationship between reaction velocity and the concentrations of the two substrates in *ping-pong bi-bi* reactions reduces to the form

$$v = \frac{V_{\max} \times [S_1] [S_2]}{[S_1] [S_2] + [S_2] K_m^1 + [S_1] K_m^2} \quad (14.18)$$

The reciprocals of v and $[S_1]$ are related by the equation

$$\frac{1}{v} = \frac{1}{[S_1]} \times \frac{K_m^1}{V_{\max}} + \frac{1}{V_{\max}} \left(1 + \frac{K_m^2}{[S_2]} \right) \quad (14.19)$$

so that a plot of $1/v$ against $1/[S_1]$ is unchanged in slope by variation in $[S_2]$, but by the intercept on the ordinate, and therefore the value of $V_{\max}$ changes as $[S_2]$ is varied. Similar equations describe the variation of $V_{\max}$ with $[S_1]$ when $1/v$ is plotted as a function of $1/[S_2]$.

Values of K_m and $V_{\max}$ for each substrate are derived from experiments in which the concentration of the first substrate is held constant at saturating quantities while the concentration of the second substrate is varied, and vice versa. The selection of reaction conditions for the measurement of enzymatic activity involving two substrates is approached similarly by varying the concentration of the first substrate and keeping the concentration of the second substrate constant until maximum activity is reached. The process is then repeated with the concentration of the first substrate held at the value thus determined, whereas the concentration of the second substrate is varied.

In practice, the choice of substrate concentrations is limited by such considerations as the solubility of the substrates, the

viscosity and initial absorbance of concentrated solutions, and the relative costs of the reagents. Furthermore, the selection of appropriate substrate concentrations is only one of the factors to consider in formulating an optimal assay system for the measurement of a certain enzyme activity. Additional, frequently interdependent factors that affect the reaction rate also include the concentrations of activators, inhibitors, the pH, and the nature of the buffer system.

Consecutive Enzymatic Reactions

As discussed previously, an enzymatic reaction is usually found to be more rapid in one direction than the other, so that the reaction is essentially irreversible. If the product of the reaction in one direction is removed as it is formed (i.e., because it is the substrate of a second enzyme present in the reaction mixture), the equilibrium of the first enzymatic process is displaced so that the reaction may continue to completion in that direction. Analytically, several enzymatic reactions may be linked together to provide a means of measuring the activity of the first enzyme or the concentration of the initial substrate in the chain.

When a linked enzyme assay, known as an *indicator reaction*, is used to determine the activity of a different enzyme, it is essential that the primary reaction be the rate-limiting step. For example, in the determination of AST activity, the indicator reaction is the reduction of the 2-oxoglutarate formed in the aminotransferase reaction to malate by malate dehydrogenase and NADH. The activity of the indicator enzyme must be sufficient to ensure the immediate removal of the product of the first reaction so as to prevent significant reversal of the first reaction. The measured enzyme typically acts under conditions of saturation with respect to its substrate; however, the concentration of the substrate of the indicator enzyme (i.e., the product of the first reaction) remains in the region of the Michaelis-Menten curve, in which v is directly proportional to $[S]$. Therefore the rate of reaction catalyzed by the indicator enzyme is directly proportional to the rate of product formation in the first reaction.

During a lag period that occurs after the start of the first reaction, the concentration of its product reaches a steady state. Because the rate of the second reaction depends on the activity of the indicator enzyme and on the concentration of its substrate (the product of the primary reaction), the duration of the lag period is reduced by increasing the concentration of the indicator enzyme, thus lowering the steady-state concentration of the product of the primary reaction.

The rate of the indicator reaction, v_i , is related to substrate concentration and therefore to the product concentration $[P]$ by the Michaelis-Menten equation

$$v_i = \frac{V_{\max}^i \times [P]}{[P] + K_m^i} \quad (14.20)$$

in which $V_{\max}^i$ and K_m^i are the maximum velocity and K_m of the indicator enzyme, respectively. For the rate of the indicator reaction not to be the rate limiting factor, v_i must at least equal the limiting velocity of the primary reaction, v_p , which the assay system is expected to measure. Therefore, the minimum activity of the indicator enzyme needed is given by

$$v_t = \frac{V_{\max}^i \times [P]}{[P] + K_m^i} \quad (14.21)$$

which can be rearranged to

$$V_{\max}^i = v_t \left(1 + \frac{K_m^i}{[P]} \right) \quad (14.22)$$

The ratio of activities of the indicator and primary enzymes varies from one assay method to another, depending on (1) the range of activity measured, (2) the K_m of the indicator enzyme, and (3) the lag period that is considered acceptable. Nevertheless, the catalytic concentration of the indicator enzyme in the reaction mixture must always be much greater than that of the enzyme being determined.

Effect of pH

The rate of an enzyme-catalyzed reaction typically shows a marked dependence on pH (Fig. 14.5). Many of the enzymes in blood plasma show maximum activity in vitro in the pH range from 7 to 8. However, activity has been observed at pH values as low as 1.5 (pepsin) and as high as 10.5 (ALP). The optimal pH for a given forward reaction may be different from the optimal pH found for the corresponding reverse reaction. The form of the pH-dependence curve is the result of a number of separate effects, including ionization of the substrate and the extent of dissociation of certain key amino acid side chains in the protein molecule, both at the active center and elsewhere in the molecule. The pH and ionic environment will also have an effect on the 3D conformation of the protein and therefore on enzyme activity to such an extent that enzymes may be irreversibly denatured at extreme pH values.

Fig. 14.5 The pH activity curves for urease show the effects of buffer species on pH optimum. (Modified from Howell, S. F., & Sumner, J. B. [1934]. The specific effects of buffers upon urease activity. *Journal of Biological Chemistry*, 104, 619.)

The pronounced effects of pH on enzyme reactions emphasize the need to control this variable by means of adequate buffer solutions. Enzyme assays should be carried out at the pH of optimal activity, because the pH-activity curve has its minimum slope near this pH, and a small variation in pH will cause a minimal change in enzyme activity. **The buffer system must be capable of counteracting the effect of adding the specimen** (e.g., serum itself is a powerful buffer) to the assay system, as well as the effects of acids or bases formed during the reaction (e.g., formation of fatty acids by the action of lipase). Because buffers have their maximum buffering capacity close to their pK_a values, whenever possible a buffer system should be chosen with a pK_a value within 1 pH unit of the desired pH of the assay. Interaction between buffer ions and other components of the assay system (e.g., the chelation of activating metal ions) may eliminate certain buffers from consideration.

Temperature

The rate of an enzymatic reaction is proportional to its reaction temperature, but only up to a certain point. For most enzymatic reactions, values of Q_{10} **(the relative reaction rates at two temperatures differing by 10°C)** vary from 1.7 to 2.5. However, an increase in the rate of the catalyzed reaction is not the only effect of increasing temperature on an enzymatic reaction. Enzyme inactivation, due to protein denaturation as the temperature increases, accounts for the existence of an apparent optimal temperature for enzyme activity (Fig. 14.6).

At some critical temperature, an enzyme will undergo thermal inactivation influenced by the presence of substrate and its concentration, the pH, and the nature and ionic strength of the buffer. The presence of other proteins, as in serum samples, may help to stabilize enzymes. Storage of serum samples at low temperatures is necessary to minimize loss of enzyme activity while awaiting analysis, although repeated freezing and thawing should be avoided. However,

individual enzymes vary in their stability characteristics, and appropriate storage conditions vary correspondingly. Serum amylase, for example, is stable at room temperature (22°C to 25°C) for 24 hours, whereas acid phosphatase is exceedingly unstable, even when refrigerated, unless kept at a pH below 6.0. ALP exhibits an unusual property; in sera stored at refrigerated temperatures, ALP increases slowly (2% per day), which is thought to be due to the reincorporation of cations required for full activity. Frozen specimens should be thawed and kept at room temperature for 18 to 24 hours before measurement to achieve full enzyme reactivation. This effect is shared by reconstituted, lyophilized preparations of the enzyme and affects their use for quality control purposes. A few enzymes are inactivated at refrigerator temperatures; a clinically important example is the liver isoenzyme of LD, LD-5, which appears to be less stable at lower temperatures. As a result, sera for LD determinations should be kept at room temperature and not refrigerated.

Most analytical systems operate at 37°C, and reference methods for several clinically relevant enzymes have now been developed at this temperature. Accurate and precise temperature control to within $\pm 0.1^\circ\text{C}$ during the enzymatic reaction is essential, and is achievable by modern instruments.

Inhibitors and Activators

The rates of enzymatic reactions are often affected by substances other than the enzyme or substrate. These modifiers may be **inhibitors** that reduce the reaction rate, or **activators** that increase the rate of reaction. Activators and inhibitors are usually small molecules (compared with the enzyme itself) or even ions. They vary in specificity from modifiers that exert similar effects on a wide range of different enzymatic reactions, to substances that affect only a single reaction. The activity of some enzymes depends on the presence of particular chemical groups, such as reduced sulfhydryl ($-\text{SH}$) groups, in the active center. Reagents that alter these groups (e.g., oxidizing agents) therefore act as general inhibitors of such enzymes.

Some phenomena of enzyme activation or inhibition are caused by interactions between the modifier and a nonenzymatic component of the reaction system, such as the substrate (e.g., magnesium $[\text{Mg}^{2+}]$ combining with ATP to form MgATP , a required substrate for the CK reaction). In most cases, however, the modifier binds to the enzyme itself, either to the active site, or to some other part of the enzyme's structure.

Inhibition of Enzyme Activity

Inhibitors are classified as reversible or irreversible. *Reversible inhibition* implies that the activity of the enzyme is fully restored when the inhibitor is removed from the system by some physical separative process, such as dialysis, gel filtration, or chromatography. An *irreversible inhibitor* combines covalently with the enzyme so that physical methods are ineffective in separating the two. For example, organophosphorus compounds are extremely potent irreversible inhibitors of esterases, including

Fig. 14.6 Schematic diagram showing the effects of temperature on the rate of non-enzyme-catalyzed and enzyme-catalyzed reactions.

acetylcholinesterase, which is the mechanism for organophosphate poisoning. The enzyme breaks one of the bonds in the inhibitor, but part of the molecule is left bound to the active center of the enzyme, preventing further activity. In some cases, enzymes that have combined with irreversible inhibitors can be reactivated by a chemical reaction that removes the blocking group (e.g., the phosphoryl enzymes formed with organophosphorus compounds can sometimes be reactivated by treatment with oximes or hydroxamic acids).

Reversible inhibition. Reversible inhibition is characterized by the existence of equilibrium between enzyme, E, and inhibitor, I:

The equilibrium constant of the reaction, K_i (the *inhibitor constant*), is a measure of the affinity of the inhibitor for the enzyme, just as K_m generally reflects the affinity of the enzyme for its substrate.

A **competitive inhibitor** is usually a structural analog of the substrate that can combine with the free enzyme in such a way that it competes with the normal substrate for binding at the active site. The rate of the reaction in the presence of a reversible inhibitor is strictly dependent on the relative concentrations of substrate and inhibitor. Two equilibria are therefore possible:

and

The equation that relates the observed reaction velocity to the concentrations of substrate, [S], and inhibitor, [I], is as follows:

$$v = \frac{V_{\max} [S]}{[S] + K_m \left(1 + \frac{[I]}{K_i}\right)} \quad (14.26)$$

This is the Michaelis-Menten equation, but with K_m modified by a term including the inhibitor concentration and the inhibitor constant, while $V_{\max}$ remains unaltered. Therefore curves of v against [S] in the presence and absence of the inhibitor reach the same limiting value at high substrate concentrations, but when the inhibitor is present, K_m is accordingly greater. Plots of $1/v$ against $1/[S]$ with and without inhibitor intersect the ordinate at the same point but have different slopes and intercepts on the abscissa (Fig. 14.7).

Competitive inhibition is responsible for the inhibition of some enzymes by excess substrate because of competition between substrate molecules for a single binding site. In two-substrate reactions, high concentrations of the second substrate may compete with binding of the first substrate. For example, AST is inhibited by excess concentrations of the substrate 2-oxoglutarate, and this inhibition is competitive with respect to L-aspartate. Therefore to maintain a given velocity at high 2-oxoglutarate concentrations, the concentration of L-aspartate has to be increased above the value needed at lower concentrations of 2-oxoglutarate.

Fig. 14.7 Effects of different types of inhibitors on the double-reciprocal plot of $1/v$ against $1/[S]$. Each of the inhibitors has been assumed to reduce the activity of the enzyme by the same amount, represented by the change in $1/v$ from a to b at a substrate concentration of c . Line O is the plot for enzyme without inhibitor, C with a competitive inhibitor, NC with a noncompetitive inhibitor, and UC with an uncompetitive inhibitor. (From Moss, D. W. [1979]. *Measurement of enzymes*. In: D. J. Hearse & J. de Leiris [Eds.], *Enzymes in cardiology: diagnosis and research*. New York: John Wiley & Sons. Reprinted by permission of John Wiley & Sons.)

Competitive inhibition also contributes to the reduction in the rate of an enzymatic reaction over time. For example, rate reduction can occur because increasing concentrations of reaction products tend to drive the reaction backward, if it is **freely reversible**. A product may be an inhibitor of the forward reaction, so even if the reaction is not readily reversible, it slows down in the presence of a rising concentration of the inhibitor. A familiar example of product inhibition is the release of the competitive inhibitor inorganic phosphate by the action of ALP on its substrates. In this case, both organic phosphates and inorganic phosphates bind to the active center of the enzyme with similar affinities (i.e., K_m and K_i are of the same order of magnitude).

Product inhibition is a cause of nonlinearity of reaction progress curves during fixed-time methods of enzyme assay. For example, oxaloacetate produced by the action of AST inhibits the enzyme, particularly the mitochondrial isoenzyme. The inhibitory product may be removed as it is formed by a coupled enzymatic reaction; malate dehydrogenase converts the oxaloacetate to malate and at the same time oxidizes NADH to NAD^+ .

Competitive inhibition by metal ions occurs when two metal ions compete for the same binding site on the enzyme. Sodium and lithium are potent inhibitors of pyruvate kinase, for which potassium is an obligatory activator.

A noncompetitive inhibitor is usually structurally different from the substrate. It is assumed to bind at a site on the enzyme molecule that is different from the substrate-binding

site; thus there is no competition between inhibitor and substrate, and a ternary enzyme substrate–inhibitor (ESI) complex is formed. Attachment of the inhibitor to the enzyme does not alter the affinity of the enzyme for its substrate (i.e., K_m is unaltered), but the ESI complex does not break down to give products. Because the substrate does not compete with the inhibitor for binding sites on the enzyme molecule, increasing the substrate concentration does not overcome the effect of a noncompetitive inhibitor. Thus $V_{\max}$ is reduced in the presence of such an inhibitor, whereas K_m is not altered, as the Lineweaver-Burk plot shows (see Fig. 14.7).

Uncompetitive inhibition is produced by a combination of the inhibitor with the ES complex. It is more common in two-substrate reactions, in which a ternary ESI complex forms after the first substrate has combined with the enzyme. In uncompetitive inhibition, parallel lines are obtained when plots of $1/v$ against $1/[S]$ with and without the inhibitor are compared (see Fig. 14.7); that is, both K_m and $V_{\max}$ are decreased.

Irreversible inhibition. Irreversible inhibitors render the enzyme molecule inactive by covalently and permanently modifying a functional group required for catalysis. An irreversible inhibitor is not in equilibrium with the enzyme. Its effect is progressive with time, becoming complete if the amount of inhibitor present exceeds the total amount of enzyme. The rate of the reaction between the enzyme and the inhibitor is expressed as the fraction of the enzyme activity that is inhibited in a fixed time by a given concentration of inhibitor. The velocity constant of the reaction of the inhibitor with the enzyme is a measure of the effectiveness of the inhibitor.

When the inhibitor is added to the enzyme in the presence of its substrate, the reaction between the enzyme and the inhibitor may be delayed because some of the enzyme molecules are combined with the substrate and are therefore protected from reacting with the inhibitor. However, when the substrate molecules react chemically, the active centers become available, and inhibition will eventually become complete, even though an excess of substrate may have been present initially. Furthermore, the addition of more substrate is ineffective in reversing the inhibition in contrast to its effect on reversible competitive inhibition.

Irreversible inhibitors have been useful in mapping active sites by covalently modifying different types of functional groups in the enzyme molecule to establish whether such groups are necessary for catalytic activity.

A physiologically important category of irreversible enzyme inhibition is exemplified by various trypsin inhibitors. These are proteins that bind to trypsin irreversibly, nullifying its proteolytic activity. One such inhibitor is present in the α_1 -globulin fraction of serum proteins; others are found in soybeans and lima beans. Similar proteolysis inhibitors present in plasma prevent the accumulation of excess thrombin and other coagulation enzymes, thus keeping the coagulation process under control.

Inhibition by antibodies. The combination of enzyme molecules with specific antibodies often has no effect on catalytic

activity, which is retained by the enzyme-antibody complex. However, in some cases, the reaction of the enzyme and antibody reduces or even abolishes enzymatic activity. The most probable explanation for this type of inhibition is that the antibody molecule restricts access of the substrate molecules to the active center by steric hindrance or, in extreme cases, completely masks the substrate-binding site. However, it appears that some examples of enzyme inhibition by combination with antibodies are caused by a conformational change induced in the enzyme molecule.

Inhibition of the activity of an enzyme molecule labeled with a hapten (e.g., morphine) as a result of combination with a specific antibody forms the basis for a homogeneous enzyme immunoassay (see Chapter 15).

Enzyme Activation

Activators increase the rates of enzyme-catalyzed reactions by promoting formation of the most active state of the enzyme or of other reactants, such as the substrate. This generalization covers a wide variety of mechanisms of activation.

Many enzymes contain metal ions as an integral part of their structures (e.g., zinc in ALP and carboxypeptidase A). The function of the metal may be to stabilize tertiary and quaternary protein structures. Removal of divalent metal ions by treatment with an appropriate quantity of ethylenediaminetetraacetic acid (EDTA) solution is accompanied by conformational changes and inactivation of the enzyme. The enzyme can often be reactivated by dialysis against a solution of the appropriate metal ion or simply by addition of the ion to the reaction mixture. Reactivation may take some time because rearrangement of polypeptide chains into the active conformation is not instantaneous.

When the activator ion is an essential part of the functional enzyme molecule, whether as a purely structural element or with an additional catalytic role, it is usually incorporated quite firmly into the enzyme molecule. Therefore it is not usually necessary to add the activator to reaction mixtures and an excess of the ion may even have an inhibitory effect. However, in some cases, the activating ion is attached only weakly or transiently to the enzyme (or its substrate) during catalysis. Enzyme samples may therefore be deficient in the ion, so that addition of the ion increases the reaction rate or indeed may be essential for the reaction to take place. For example, all phosphate transfer enzymes (kinases), such as CK, require the presence of Mg^{2+} ions. Other common activating cations are manganese (Mn^{2+}), iron (Fe^{2+}), calcium (Ca^{2+}), zinc (Zn^{2+}), and potassium (K^+). More rarely, anions may act as activators. Amylase functions at its maximal rate only if chloride (Cl^-) or other monovalent anions, such as bromide (Br^-) or nitrate (NO_3^-), are present. Addition of 5 mmol/L of chloride increases amylase activity almost threefold, at the same time shifting the pH optimum from 6.5 to 7.0. The Cl^- ion may combine with a positively charged group in the enzyme, changing the ionization constant of a group important in catalysis. Some enzymes require the presence of two activating ions. K^+ and Mg^{2+} are essential for the activity of pyruvate kinase, and both Mg^{2+} and Zn^{2+} are required for ALP activity.

The velocity of the reaction depends on the concentration of a reversible activator in a fashion similar to its dependence on substrate concentration. An activator constant, K_a , analogous to K_m , can be determined from data relating enzyme activity to increasing activator concentration in the presence of excess substrate. The simplest interpretation of K_a is that it is the dissociation constant of the equilibrium between E and the activator, A. However, this is true only when the combination of enzyme and activator is independent of the reaction between E and S, and the same value for K_a is obtained at all concentrations of the substrate. If the free enzyme and the ES complex have different affinities for the activator, the value for K_a varies with [S].

Apparent activation of an enzyme may be observed whenever a substance that can counteract the presence of some inhibiting agent is added.

Coenzymes and Prosthetic Groups

Coenzymes are usually more complex molecules than activators, although they are smaller molecules than the enzyme proteins. Some compounds, such as the dinucleotides NAD and NADP, are classified as coenzymes and are specific substrates in two-substrate reactions. Their effects on the rate of reaction follow the Michaelis-Menten pattern of dependence on substrate concentration. The structures of these two coenzymes are identical except for the presence of an additional phosphate group in NADP; nevertheless, individual dehydrogenases, for which these coenzymes are substrates, are predominantly or even absolutely specific for one or the other form.

Coenzymes such as NAD and NADP are bound only momentarily to the enzyme during the course of the reaction, as is the case for substrates in general. Therefore no reaction takes place unless the appropriate coenzyme is present in solution (e.g., by adding it to the reaction mixture in the assay of dehydrogenase activity). In contrast to these entirely soluble coenzymes, some coenzymes are more or less permanently bound to the enzyme molecules, where they form part of the active center and undergo cycles of chemical change during the reaction. In this case, the coenzyme is known as a prosthetic group. Prosthetic groups, such as activators with a structural role, do not usually have to be added to elicit full catalytic activity of the enzyme unless previous treatment has caused the prosthetic group to be lost from some enzyme molecules.

The active *holoenzyme* results from the combination of the inactive *apoenzyme* with the prosthetic group. An example of a prosthetic group is pyridoxal-5'-phosphate (P-5'-P), a component of AST and ALT. The P-5'-P prosthetic group undergoes a cycle of conversion of the pyridoxal moiety to pyridoxamine and back again during the transfer of an amino group from an amino acid to an oxoacid. However, both normal and pathologic serum samples contain appreciable quantities of apoaminotransferases, which are converted to active holoenzymes through a suitable period of incubation with P-5'-P.

A study of the formulas of coenzyme and prosthetic groups shows that many contain structures derived from vitamins (see Chapter 27). Thus the nicotinamide portion of NAD and NADP derives from the vitamin niacin, whereas the P-5'-P prosthetic group of the aminotransferases is a derivative of pyridoxine, vitamin B₆.

POINTS TO REMEMBER

- The catalytic properties of enzymes can be described by equations based on the formation of an ES complex.
- Enzyme reactions are affected by temperature, pH, enzyme concentration, substrate concentration, and the presence of any inhibitors or activators.

ANALYTICAL ENZYMOLOGY

Analytically, the clinical laboratorian is concerned with measuring the activity or mass of enzymes in serum or plasma that are predominantly intracellular, and that are physiologically present in the serum in low concentrations only. By measuring changes in the concentrations of these enzymes in disease, it is possible to infer the location and nature of pathologic changes in body tissues.

Measurement of Reaction Rates

Both *fixed-time* and *continuous-monitoring* methods are used to measure reaction rates. In the fixed-time method, the amount of product produced from substrate by the enzyme is measured after the reaction is stopped at the end of a fixed-time interval. In the continuous-monitoring method, the rate of product formation is monitored as the reaction is proceeding. These two methods have different advantages and limitations. To appreciate them, it is necessary to consider the way in which the rate of an enzymatic reaction varies with time.

The progress of conversion of the substrate into products in the presence of an enzyme is monitored by measuring the decreasing concentration of the substrate or the increasing concentration of the products. Measurement of product formation is preferable because determination of the increase in concentration of a substance above an initially zero or low concentration is analytically more reliable than measurement of a decline from an initially high concentration.

At the moment when the enzyme and the substrate are mixed, the rate of the reaction is zero. The rate then typically rises rapidly to a maximum value, which remains constant for a period of time (Fig. 14.8). During the period of constant reaction rate, the rate depends only on enzyme concentration and is completely independent of substrate concentration. The reaction is said to follow zero-order kinetics, because its rate is proportional to the zero power of the substrate concentration. Ultimately, however, as more substrate is consumed, the reaction rate declines and enters a phase of first-order dependence on substrate concentration. Other factors that contribute to the decline in reaction rate include accumulation of products that may be inhibitory, the growing importance of the reverse reaction, and even enzyme denaturation. Enzyme assays are

Fig. 14.8 Changes in substrate concentrations and rates of reaction during an assay of lactate dehydrogenase activity at 37°C in phosphate buffer, with pyruvate and nicotinamide adenine dinucleotide (NADH) as substrates. The reaction is followed by observing the fall in absorbance at 340 nm as NADH is oxidized to NAD⁺. The rate of reaction rises rapidly to a maximum value, from which it declines only slightly until about half the NADH has been used up. During this phase of the reaction, the rate is essentially zero order with respect to substrate concentration. At the point at which the rate falls below about 90% of its maximum value, NADH concentration is approximately $10 \times K_m$. The K_m for NADH is on the order of 5×10^{-6} mol/L, whereas for pyruvate it is 9×10^{-5} mol/L. Thus an initial pyruvate concentration approximately 10 times that of NADH is used. (Concentrations are per liter of reaction mixture.) (From Moss, D. W. [1979]. *Measurement of enzymes*. In: D. J. Hearse & J. de Leiris [Eds.], *Enzymes in cardiology: diagnosis and research*. New York: John Wiley & Sons. Reprinted by permission of John Wiley & Sons.)

usually made under conditions that are initially saturating with respect to substrate concentration. The rate of reaction during the zero-order phase is determined by measuring the product formed during a fixed period of incubation in which the rate remains constant. This is illustrated in Fig. 14.9. Measurement of reaction rates at any portion of curve A gives results that are identical to the true *initial rate*. However, curve B deviates from linearity over its entire course, and rates fall off with time. From curve C, correct results are obtained only if the rate is measured along segment II. Incorrect results are obtained if the rate is measured during the lag phase (I) or during the phase of substrate depletion (III).

Careful selection of reaction conditions, such as the concentrations of substrates and cofactors, improves the reaction progress curves, eliminates lag phases, and prolongs the period of zero-order kinetics, so that fixed-time methods of analysis become feasible. Improvements in optical techniques, leading to more reliable and sensitive measurement of product formation, also have allowed the duration of incubation to be shortened compared with that of older assays. Nevertheless, an upper limit of activity exists in all fixed-time methods, above which progress curves will no longer be linear. In this case, the amount of change measured over the fixed-time interval no longer represents true zero-order rate conditions.

The upper limit of activity must be chosen so samples with activities below it are presumed, with a high degree of certainty, to give linear progress curves; alternatively, if the limit is set too low, many samples will have to be diluted and reanalyzed unnecessarily. Samples that are above the limit should ideally be assayed again after shortening the incubation period until a constant reaction rate is obtained. However, this is difficult or impossible in some automated methods, in

Fig. 14.9 Graphs showing change in enzyme reaction rate as a function of time. (A) The rate is constant during the entire run, and rates calculated as I, II, and III will be identical to the initial rate. (B) The rate falls off continuously; rates calculated at I, II, and III will be different and less than the true initial rate. (C) A measurement at II will be representative of the maximum rate, but at I (lag period) and III (substrate depletion), it will be less than at II.

which the duration of incubation is fixed by the configuration of the apparatus. It then becomes necessary to dilute the specimen to obtain valid results. However, some diluents can cause matrix-related alterations to the reaction kinetics, and may not always result in a proportional change in activity.

The initial rate of reaction theoretically increases without limit as enzyme concentration increases, as long as no other factor, such as substrate concentration, becomes limiting. In practice, the reaction rate becomes so rapid at high enzyme activities that it is impossible to measure the initial rate of reaction, even with continuous monitoring methods. Therefore an upper limit of activity that is measurable without modification of the assay procedure exists even in continuous monitoring methods; but this limit is usually much higher than those observed in fixed-time methods. Therefore fewer samples require special treatment when using continuous monitoring methods. Furthermore, continuous monitoring allows identification of the appropriate zero-order portion of the progress curve for each sample and identification of samples that require special treatment. Continuous-monitoring methods therefore provide a decisive advantage in enzyme assay and should be used whenever possible.

Measurement of Substrates

The amount of substrate transformed into products during an enzyme-catalyzed reaction can be measured with any appropriate analytical method, such as spectrophotometry, fluorometry, or chemiluminescence (see [Chapter 9](#)). *Self-indicating* reactions of this type are particularly valuable because they allow continuous monitoring. Important examples of self-indicating reactions are determination of dehydrogenase activity by monitoring the change in absorbance at 339 (340) nm of the coenzyme NADH or NADPH during oxidation or reduction, and measurement of ALP activity by the generation of the yellow *p*-nitrophenolate ion from the substrate *p*-nitrophenyl phosphate in alkaline solution. These indicator reactions are so versatile that dehydrogenase reactions are frequently coupled to the product of a primary reaction, to provide a measurable absorbance change when the primary product does not possess a strong specific absorptivity.

The introduction of prism or diffraction-grating spectrophotometers capable of isolating a narrow beam of monochromatic light in the ultraviolet or visible spectrum, and stable and sensitive photomultipliers as detectors, greatly improved the reproducibility of photometric measurements (see [Chapter 9](#)). Consequently, it is customary to make use of the known molar absorptivity of well-defined reaction products (such as NADH) when calculating changes in their concentrations based on measurements made with spectrophotometers.

Optimization and Standardization

To measure enzyme activity reliably, all factors that affect the reaction rate—other than the concentration of active enzyme—need to be optimized and rigidly controlled. When the reaction velocity is at or near its maximum under optimal conditions, a larger analytical signal is obtained, making

more accurate and precise results possible than with the smaller signal obtained under suboptimal conditions. Much effort therefore has been devoted to determining optimal conditions for measuring the activities of enzymes of clinical importance.

Optimization

Optimization of reaction conditions for enzyme assays has traditionally been carried out by varying a single factor and studying its effect on the reaction rate, then repeating the experiment with a second factor and so on, until effects of all the variables have been tested. An optimal combination of variables is selected on the basis of these experiments, and the validity of the chosen conditions is verified. Not only is this approach labor intensive, it is also difficult to adapt in situations in which the effects of different variables are interdependent, as is frequently the case in enzyme analysis. This traditional empirical approach to optimization has been replaced by techniques of simplex cooptimization and response surface methodology.

Standardization

Current enzyme standardization efforts are focused on the development of a system that allows comparability of test results, independent of the measurement method. To achieve this, a reference measurement system based on the concepts of metrologic traceability and on the hierarchy of analytical methods has been developed. A reference procedure and certified reference materials form the basis of the metrological traceability chain ([Fig. 14.10](#)). As part of this hierarchy, reference procedures at 37°C for the most common enzymes have been developed, and manufacturers have used these as the basis of their commercial methods.

For a reference system to be capable of standardizing the results of different assays of a given enzyme activity, some conditions must be satisfied. First, the reference procedure used to assign the value of a reference material and the field method(s) to be calibrated must have similar, if not identical, specificities for the analyte enzyme, isoenzyme, or isoform under study. Second, the calibrator material must be “commutable” with natural human serum, so that the numerical relationship between enzyme concentration and measured enzyme activity is the same in the calibrators as it is in human serum.

Measurement of Enzyme Mass Concentration

Many immunoassays for human enzymes and isoenzymes that measure protein mass instead of catalytic activity have been described. To develop such assays, purified enzyme protein has to be prepared to (1) act as a calibrator, (2) be labeled, and (3) be used to raise the enzyme-specific antibody. These methods identify all molecules with the antigenic determinants necessary for recognition by the antibody, so that inactive enzyme molecules that are immunologically unaltered are measured along with active molecules. In the majority of cases, however, no degradation or changes in the active enzyme occur in blood so that the clinical equivalence of the

Fig. 14.10 The proposed reference system for enzyme measurement showing the traceability of the laboratory result to the reference measurement procedure. IFCC, The International Federation of Clinical Chemistry and Laboratory Medicine. (From Panteghini, M., Ceriotti, F., Schumann, G., & Siekmann, L. [2001]. Establishing a reference system in clinical enzymology. *Clinical Chemistry and Laboratory Medicine*, 39, 795–800. Reprinted with permission of Walter de Gruyter.)

different measurement approaches (i.e., estimation of catalytic activity and mass concentration) is obtained.

Immunoassays typically are not used for determination of total activities for the more important diagnostic enzymes because these assays generally cannot compete in terms of speed, precision, and cost with automated measurements of catalytic activity. Furthermore, several enzyme activities in serum are due to mixtures of immunologically distinct forms, so an assay using a single type of antibody usually determines only one of the enzyme forms. However, this disadvantage in the determination of total enzyme activity becomes a marked advantage in the measurement of specific isoenzymes and isoforms, and immunologic methods have been used routinely in the isoenzyme analysis of CK, amylase, and ALP.

Enzymes as Analytical Reagents

Enzymes are used as analytical reagents for measurement of several metabolites and substrates and in immunoassays to detect and quantify immunologic reactions.

Measurement of Metabolites

The use of enzymes as analytical reagents to measure metabolites frequently offers the advantage of great specificity for the substance being determined. This high specificity typically removes the need for preliminary separation or purification steps, so the analysis can be carried out directly on complex

mixtures such as serum. Uricase (urate oxidase), urease, and glucose oxidase are examples of highly specific enzymes used in clinically important assays, such as the measurement of uric acid, urea, and glucose in biological fluids. However, high specificity cannot always be achieved in practice, and knowledge of the substrate specificities of reagent enzymes is essential to identify possible interferences with the assay, and to correct for them if possible. Coupled reactions are often necessary to construct an enzymatic assay for a specific compound. For example, in the enzymatic determination of glucose, hexokinase converts a number of sugars to their 6-phosphate esters. However, the indicator reaction used to monitor this change uses glucose-6-phosphate dehydrogenase, which is highly specific for glucose-6-phosphate, rendering the assay highly specific for glucose.

Equilibrium methods. Most assays used to determine the amount of a substance enzymatically are allowed to continue to completion, so that all substrate has been converted into a measurable product. These methods are called *end point* or, more correctly, *equilibrium* methods, because the product concentration no longer increases when equilibrium is reached. Reactions in which the equilibrium point corresponds virtually to complete conversion of the substrate to product are obviously preferable for this type of analysis. However, an unfavorable equilibrium often can be overcome by additional enzymatic or nonenzymatic reactions that convert or trap a product of the first reaction. Removing one of the products of the reaction keeps the system in disequilibrium, allowing for nearly total conversion of substrate into product. For example, when measuring lactate with LD, the pyruvate formed can be trapped by the addition of hydrazine, with which it forms an irreversible hydrazone, preventing the pyruvate from causing product inhibition of the LD reaction.

Theoretically, the time required to transform a fixed quantity, Q , of substrate into products is inversely proportional to the amount of enzyme, $[E]$, present:

$$Q = k_1 \times [E] \times t \quad (14.27)$$

and

$$[E] = \frac{Q}{k_1} \times \frac{1}{t} \quad (14.28)$$

where k_1 is the rate constant and t is the elapsed time. Equilibrium methods may therefore require the use of appreciable amounts of enzyme for each sample, to avoid inconveniently long incubation periods. As the substrate concentration falls to low quantities toward the end of the reaction, the K_m of the enzyme becomes important in determining the reaction rate. Enzymes with high affinities for their substrates (low K_m values) are most suitable for equilibrium analysis. Equilibrium methods are largely insensitive to minor changes in reaction conditions, so it is not necessary to have exactly the same amount of enzyme in each reaction mixture or to maintain the pH or temperature absolutely constant, provided that the variations are not so great that the reaction is not completed within the fixed time allowed.

Kinetic methods. First-order or pseudo-first-order reactions are the most important reactions for the kinetic

determination of substrate concentration. For any first-order reaction, the substrate concentration $[S]$ at a given time t after the start of the reaction is given by

$$[S] = [S_0] \times e^{-kt} \quad (14.29)$$

where $[S_0]$ is the initial substrate concentration, e is the base of the natural log, and k is the rate constant.

The change in substrate concentration $\Delta[S]$ over a fixed time interval, t_1 to t_2 , is related to $[S_0]$ by the equation

$$[S_0] = \frac{-\Delta[S]}{e^{-kt_1} - e^{-kt_2}} \quad (14.30)$$

As this equation indicates, the change in substrate concentration over a fixed time interval is directly proportional to its initial concentration. This is a general property of first-order reactions.

For an enzymatic reaction, **first-order kinetics** is followed when $[S]$ is small compared with K_m . Thus

$$v = \frac{V_{\max}}{K_m} \times [S] \quad (14.31)$$

or

$$v = k[S] \quad (14.32)$$

Therefore the first-order rate constant, k , is equal to $\frac{V_{\max}}{K_m}$.

Methods in which some property related to substrate concentration (e.g., absorbance, fluorescence, chemiluminescence) is measured at two fixed times during the course of the reaction are known as *two-point* kinetic methods. Theoretically, they are most accurate for the enzymatic determination of substrates. However, these methods are technically more demanding than equilibrium methods and all factors that affect reaction rate, such as pH, temperature, and amount of enzyme, must be kept constant from one assay to the next, as must the timing of the two measurements. These conditions can be readily achieved in automated analyzers. A reference solution of the analyte (substrate) is used for calibration. To ensure first-order reaction conditions, the substrate concentration must be low compared with the K_m (i.e., in the order of less than $0.2 \times K_m$). Enzymes with high K_m values are therefore preferred for kinetic analysis to obtain a wider usable range of substrate concentrations.

Immunoassay

In enzyme immunoassay, enzyme-labeled antibodies or antigens are first allowed to react with a ligand; then an enzyme substrate is added. Enzymes such as ALP have been used as enzyme labels. A modification of this methodology is the enzyme-linked immunosorbent assay (ELISA), in which one of the reaction components is bound to a solid-phase surface. In this technique, an aliquot of sample is allowed to interact with the solid-phase antibody. After washing, a second antibody labeled with enzyme is added to form an Ab–Ag–Ab–enzyme complex. Excess free enzyme-labeled antibody is then washed away, and the substrate is added; the conversion of substrate is proportional to the quantity of antigen. In immunoassays, it is not the specificity of labeled enzymes that is important, but rather their sensitivity.

Analytical Applications of Immobilized Enzymes

For some types of enzymatic analyses, enzyme consumption is reduced by the use of immobilized enzymes that are reused for several analyses. Immobilized enzymes have been chemically bonded to adsorbents such as (1) microcrystalline cellulose, (2) diethylaminoethyl (DEAE) cellulose, (3) carboxymethyl cellulose, and (4) agarose. Diazo, triazine, and azide groups are used to join the enzyme protein to the insoluble matrix, forming particles in contact with the substrate solution or a surface in contact with substrate solution, such as a membrane or a coating on the inner surface of a vessel holding the substrate solution. Among enzymes available in such immobilized form are (1) urease, (2) hexokinase, (3) α -amylase, (4) glucose oxidase, (5) trypsin, and (6) leucine aminopeptidase. Immobilized enzymes are generally more stable than enzymes in solution; but some properties of the enzyme, such as its K_m or its pH optimum, may be altered.

Electrochemical techniques such as (1) potentiometry, (2) polarography, and (3) microcalorimetry have been adapted to exploit the benefits of immobilized enzymes. Enzymes incorporated into membranes form part of enzyme electrodes such as on blood gas analyzers. The surface of an ion-sensitive electrode is coated with a layer of porous gel in which an enzyme has been polymerized. When the electrode is immersed in a solution of the appropriate substrate, the action of the enzyme produces ions to which the electrode is sensitive.

Measurement of Isoenzymes and Isoforms

A number of analytical techniques have been used to measure specific isoenzymes or isoforms including (1) electrophoresis (see Chapter 11), (2) chromatography (see Chapter 12), (3) chemical inactivation, and (4) differences in catalytic properties, but the most widely used methods are now based on immunochemical principles (see Chapter 15).

Electrophoresis

Various forms of electrophoresis have been used to separate isoenzymes. The methods are time-consuming, difficult to quantify, and relatively expensive and thus tend to be restricted to larger, reference laboratories.

Chromatography

Ion-exchange chromatography makes use of differences in net molecular charge at a given pH to separate isoenzymes. A typical ion-exchange material is DEAE cellulose, in which ionizable DEAE groups are attached to an inert cellulose matrix. Ion-exchange chromatography, in general, lacks the resolving power of electrophoresis, but relatively large quantities of proteins can be separated with good recovery of enzymatic activity; so the method is of great value in enzyme purification.

Other forms of chromatography that have been applied to fractionation of isoenzyme mixtures include high-performance liquid chromatography and affinity chromatography. The latter makes use of differences between isoenzymes in their affinities for a specific ligand that is attached to an inert insoluble support used as the stationary phase in a chromatography column or in a batch technique.

Immunochemical Assays

Immunochemical methods of isoenzyme analysis are particularly applicable to isoenzymes derived from multiple genes because these are usually most clearly antigenically distinct. However, the greater discriminating power of monoclonal antibodies has potentially brought all multiple forms of an enzyme within the scope of immunochemical analysis. Some of these methods detect catalytic activity of the isoenzymes. For example, residual activity may be measured after reaction with antiserum. Radioimmunoassays in which isoenzyme labeled with a radioactive tracer competes with unlabeled isoenzyme for antibody-binding sites have been applied in the past to isoenzyme measurement. However, with the development of automated immunoassay systems, the preferred method for measuring isoenzymes in the clinical laboratory

is a solid-phase sandwich ELISA assay because of its convenience and relative low cost. These methods do not depend on the catalytic activity of the isoenzyme being determined.

The choice and application of various methods of isoenzyme analysis in clinical enzymology in relation to specific isoenzyme systems are discussed in [Chapter 19](#).

POINTS TO REMEMBER

- Because of their specificity, enzymes can be used as analytical reagents to measure compounds such as metabolites in complex mediums.
- The measurement of isoenzymes increases the diagnostic specificity and sensitivity of enzyme assays in body fluid samples.

REVIEW QUESTIONS

- The enzyme 2.2.8.11 is a(n):
 - oxidoreductase.
 - transferase.
 - hydrolase.
 - lyase.
 - isomerase.
 - ligase.
- A disulfide bond in a protein is an example of:
 - primary structure.
 - secondary structure.
 - tertiary structure.
 - quaternary structure.
- The active site of an enzyme is:
 - small compared to the entire enzyme.
 - usually in the center of the enzyme.
 - not specific for inhibitors.
 - typically only involves a few continuous bases along the primary structure.
- Which of the following can affect the rate of an enzyme-catalyzed reaction?
 - Enzyme concentration
 - Substrate concentration
 - pH
 - Reaction temperature
 - All of the above
- K_m is:
 - the enzyme concentration that results in 50% of the maximal reaction rate.
 - a property of an enzyme and substrate under certain conditions.
 - a property of an enzyme irrespective of the substrate.
 - a property of a substrate irrespective of the enzyme.
- Which statement is correct?
 - Either the enzyme or the coenzyme, but not both, are consumed during an enzymatic reaction.
 - An enzyme without a prosthetic group attached is referred to as a coenzyme.
 - Coenzymes may contain vitamins.
 - All of the above statements are correct.
- An enzyme assay determined by a single measurement taken at the termination of the enzymatic reaction is referred to as a:
 - fixed-time assay.
 - terminator assay.
 - kinetic assay.
 - continuous-monitoring assay.
- A reactant in a catalysis reaction that binds to the enzyme's active site is the:
 - enzyme.
 - product.
 - substrate.
 - coenzyme.
- An international unit (U) of enzyme activity is the amount of enzyme that will catalyze the reaction of:
 - one micromole of substrate per minute.
 - one mole of substrate per second.
 - one micromole of enzyme per hour.
 - one millimole of substrate per minute.
- In what kind of inhibition is the inhibitor usually a structural analog of the substrate?
 - Competitive
 - Noncompetitive
 - Uncompetitive
 - Racemic mirroring
- In an analytical enzymatic measurement of substrate, an enzyme reaction is accompanied by a change in absorbance of one component of the assay system. If this change is continuously monitored while it is occurring, the reaction is referred to as a(n):
 - fixed-time reaction.
 - end point assay.
 - rate-limiting reaction.
 - self-indicating reaction.

Immunochemical Techniques

Larry J. Kricka, Jason Y. Park

OBJECTIVES

1. Define the following:
 - Affinity
 - Antibody
 - Antigen
 - Avidity
 - Hapten
 - Immunoassay
 - Immunogen
 - Monoclonal antibody
 - Polyclonal antiserum
 - Sandwich immunoassay
2. Diagram, label, and state the function of the components of an immunoglobulin G antibody molecule.
3. List three binding forces that act to produce antigen/antibody binding.
4. Explain how the following factors affect antigen/antibody binding:
 - Addition of a linear polymer
 - Ion species
 - Precipitin reaction
5. For each of the following qualitative immunochemical techniques, state the principle and clinical use:
 - Immunofixation
 - Western blotting
6. For each of the following quantitative immunochemical techniques, state the principle and clinical use:
 - Nephelometry
 - Turbidimetry
7. List five types of nonisotopic labels used in a labeled immunochemical assay, and provide one example of each type of label.
8. Compare competitive with noncompetitive immunoassays, including procedure, assay components, and uses in the clinical laboratory. Do the same for heterogeneous and homogeneous immunoassays.
9. For each of the following immunochemical techniques, state the principle, the components of each assay, the type of assay, and the clinical uses:
 - Cloned enzyme donor immunoassay
 - Enzyme-linked immunosorbent assay
 - Enzyme-multiplied immunoassay
 - Fluoroimmunoassay
 - Immunocytochemistry
10. Describe three factors that can adversely affect immunoassay results.

KEY WORDS AND DEFINITIONS

Affinity Energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen.

Antibody Immunoglobulin (Ig) class of molecule (e.g., IgA, IgG, IgM) that binds specifically to an antigen or hapten.

Antigen Any material capable of reacting with an antibody without necessarily being capable of inducing antibody formation.

Avidity Overall strength of binding of antibody and antigen; includes the sum of the binding affinities of all individual combining sites on the antibody.

Competitive immunoassay An immunoassay in which all reactants are simultaneously or sequentially mixed together and unlabeled antigen competes with labeled antigen for binding sites on the antibody.

Hapten A chemically defined determinant that, when conjugated to an immunogenic carrier, stimulates the synthesis of antibody specific for the hapten.

Heterogeneous immunoassay An immunochemical reaction in which it is assumed that the formation of the antigen/antibody complex occurs more quickly than the breakdown of the complex into antigen and antibody; in this assay, the antigen is labeled and separation of the free from the bound labeled antigen is required.

Homogeneous immunoassay An immunochemical reaction in which the activity of the label attached to the antigen is modulated directly by antibody binding; this assay does not require a separation.

Hook effect A phenomenon occurring with certain immunoassays due to very high concentrations of a particular analyte; it results in a false-negative result. The hook effect mostly affects one-step immunometric assays.

Immunoassay An assay based on the reaction of an antigen with an antibody specific for the antigen.

Immunogen A substance capable of inducing an immune response.

Label Any substance with a measurable property attached to an antigen, antibody, or binding substance.

Noncompetitive immunoassay An immunoassay in which a capture antibody is bound to a surface with subsequent antigen binding followed by the addition of a second

labeled antibody that reacts with the initial antigen/antibody complex.

Western blotting Membrane-based assay in which proteins are separated by electrophoresis, which is followed by transfer to a membrane and probing with a labeled antibody.

BASIC CONCEPTS AND DEFINITIONS

An **antigen** is any material capable of reacting with an antibody. With **immunoassays**, the antigen is the analyte of clinical interest that is being measured. **Antibodies** are immunoglobulins that bind specifically to a wide array of natural and synthetic antigens, such as (1) proteins, (2) carbohydrates, (3) nucleic acids, (4) lipids, and (5) other molecules. Analytically, immunoglobulin (Ig)G is the most prevalent immunochemical reagent in use. It is a glycoprotein that has a molecular weight (MW) of 158,000 Da and is composed of two duplex chains, with each set composed of a heavy (γ) and a light (λ or κ) chain joined by disulfide bonds (Fig. 15.1). Interchain disulfide bonds hold the duplex chains together and create a symmetrical molecule. The variable amino acid sequence at the amino terminal

end of each chain determines the antigenic specificity of the particular antibody. Each unique amino acid sequence is a product of a single plasma cell line or clone, and each plasma cell line produces antibodies with single specificities. A complex antigen elicits a multiplicity of antibodies with different specificities derived from different cell lines. An antibody developed in this manner is termed *polyclonal* and exhibits diverse specificities in its reactivity with the immunogen. Each unique region of the molecular antigen that binds a complementary antibody is termed an *epitope* (antigenic determinant).

An **immunogen** is a protein or a substance coupled to a carrier, usually a protein. Introduction of an immunogen into a foreign host induces the formation of an antibody. A **hapten** is a chemically defined determinant that by itself will not

Fig. 15.1 Schematic diagram of immunoglobulin G (IgG) antibody molecule showing carbohydrate (Cbh), disulfide bonds (SS), and major fragments produced by proteolytic enzyme treatment ($F(ab')_2$, Fc, Fab, Fd).

stimulate an immune response. However, when conjugated to an immunogenic carrier, the conjugated molecule stimulates the synthesis of antibody specific for the hapten. Some general properties required for immunogenicity include the following:

1. Areas of structural stability within the molecule
2. Randomness of structure
3. Minimum MW of 4000 to 5000 Da
4. Ability to be metabolized (a necessary but insufficient criterion for some classes of antigens)
5. Accessibility of a particular immunogenic configuration to the antibody-forming mechanism
6. Structurally foreign quality

The strength or energy of interaction between the antibody and the antigen is described in two terms. **Affinity** refers to the thermodynamic quantity defining the energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen. **Avidity** refers to the overall strength of the binding of antibody and antigen and includes the sum of the binding affinities of all individual combining sites on the antibody. Thus affinity is a property of the substance bound (antigen), and avidity is a property of the binder (antibody).

Polyclonal antiserum is produced in a normal animal host in response to immunogen administration. In contrast, a *monoclonal antibody* is the product of a single clone or plasma cell line rather than a heterogeneous mixture of antibodies produced by many cell clones in response to immunization. Monoclonal antibodies now are used widely as reagents in immunoassay techniques.

Monoclonal antibodies provide an analytical advantage in that two different antibody specificities can be used in a single assay. For example, a solid phase antibody specific for a unique epitope and another labeled antibody specific for a different epitope are reacted with antigen in a single incubation step. This combination eliminates (1) the two-step sequential addition of antigen and labeled antibody to the solid phase, (2) one incubation step, and (3) one washing step, which would be necessary when polyclonal antibodies binding to both sites are used.

ANTIGEN-ANTIBODY BINDING

In this section, several of the factors that affect the binding of antigens and antibodies are discussed.

Binding Forces

Several forces act cooperatively to produce antigen-antibody binding. The three major contributing forces are (1) electrostatic van der Waals–London dipole-dipole interactions, (2) hydrophobic interactions, and (3) ionic coulombic bonding (primarily between carboxylate and protonated amino groups on the antigen and the antibody).

Reaction Mechanism

The binding of antigen to antibody is not static but is an equilibrium reaction that proceeds in three phases. The initial

reaction (phase 1) of a multivalent antigen (Ag_n) and a bivalent antibody (Ab) occurs very rapidly in comparison with subsequent growth of the complexes (phase 2) and is depicted by the following equation:

where $k_1 \gg k_2$, n is the number of epitopes per molecule, and a and b are the numbers of antigen and antibody molecules per complex. Phase 3 of the reaction involves the precipitation of the complex after a critical size is reached. The speed of these reactions depends on electrolyte concentration, pH, and temperature, as well as on antigen and antibody types and the binding affinity of the antibody.

Precipitin Reaction

The curve shown in Fig. 15.2 is a schematic diagram of the classic precipitin curve. Although the concentration of total antibody is constant, the concentration of free antibody, $[\text{Ab}]_f$, and of free antigen, $[\text{Ag}]_f$, varies for any given Ag/Ab ratio. A low Ag/Ab ratio exists in Fig. 15.2A (zone of antibody excess). Under these conditions, excess Ab is free in solution, but all Ag is bound and immune complexes are small. As total antigen increases, the size of the immune complexes increases up to equivalence (see Fig. 15.2B), and little or no $[\text{Ab}]_f$ or $[\text{Ag}]_f$ exists. This is the zone of equivalence, and it is the optimal combining ratio for cross-linking. As Ag/Ab further increases (see Fig. 15.2C), the immune complex size decreases and $[\text{Ag}]_f$ increases (zone of antigen excess).

Chemical Factors

Chemical factors that influence antibody-antigen binding include ionic species, ionic strength, and polymeric molecules.

Fig. 15.2 Schematic diagram of precipitin curve illustrating different antigen concentration zones. A, Antibody excess. B, Equivalence. C, Antigen excess. The parameter measured may be the quantity of protein precipitated, light scattering, or another measurable parameter. Antibody concentration is held constant in this example.

Ion Species and Ionic Strength Effects

Cationic salts inhibit antibody binding to a cationic hapten. The order of inhibition by various cations corresponds to their decreasing ionic radius and the increasing radius of hydration (e.g., $\text{Cs}^+ > \text{K}^+ > \text{Li}^+$). For anionic haptens and anionic salts, the order of inhibition of binding again follows the order of decreasing ionic radius and increasing radius of hydration (e.g., $\text{SCN}^- [\text{thiocyanate}] > \text{I}^- > \text{F}^-$).

Polymer Effect

The addition of a linear polymer to a mixture of antigen and antibody causes a significant increase in the rate of immune complex growth and enhances the precipitation of immune complex, especially with low-avidity antibody. This is due to the increased probability of contact between the antigen and antibody caused by the presence of large polymer molecules in solution (steric exclusion). The most desirable characteristics of the polymer are high (1) MW, (2) degree of linearity (minimum branching), and (3) aqueous solubility. Polyethylene glycol 6000 has these characteristics and is particularly useful in immunochemical methods at concentrations of 3 to 5 g/dL.

QUALITATIVE METHODS

Immunochemical techniques used for qualitative purposes include (1) immunofixation (IF) and (2) Western blotting.

IF has gained widespread acceptance as an immunochemical method used to identify proteins. With this technique, electrophoresis is first performed in an agarose gel to separate the proteins in the mixture. Subsequently, antiserum spread directly on the gel causes the protein(s) of interest to precipitate. The immune precipitate is trapped within the gel matrix, and all other nonprecipitated proteins are then removed by washing of the gel. The gel then is stained for identification of the proteins. The utility of IF, which now is used widely for the evaluation of myeloma proteins, is illustrated in Fig. 15.3.

Blotting

The previously discussed techniques use direct examination of immunoprecipitation of the protein(s) in the gel. However, certain media, such as polyacrylamide, do not lend themselves to direct immunoprecipitation, nor does sufficient antigen concentration always exist to produce an immunoprecipitate that is retained in the gel during subsequent processing. Under these circumstances, the technique of **Western blotting** is used. This technique involves an electrophoresis step, followed by transfer of the separated proteins onto an overlying strip of nitrocellulose or nylon membrane by a process called *electroblotting*. Once the proteins are fixed to the membrane, they are detected with antibody probes labeled with molecules such as enzymes. With the use of such probes, the limits of detection are 10 to 100 times lower than the values obtained through direct immunoprecipitation and staining of proteins.

An example of blotting analysis for human immunodeficiency virus type 1 (HIV-1) antibodies is shown in Fig. 15.4.

When applied to antigen assays, concentrations of antigen as low as 500 ng/mL or 2.5 ng per band in the gel have been detected. The detection limit of the technique is lowered even farther to approximately 100 pg by chemiluminescent detection of the enzyme-labeled antibody.

Core proteins (GAGs, group-specific antigens) p18, p24, and p55; polymerase p32, p51, and p65; and envelope proteins gp41, gp120, and gp160. (Courtesy Bio-Rad Laboratories Diagnostics Group, Hercules, CA.)

A simpler technique that bypasses the electrophoretic separation step is known as *dot blotting*. A protein sample to be analyzed is applied to a membrane surface as a small “dot” and is dried. The membrane then is exposed to a labeled antibody specific for the test antigen contained in the dotted mixture. After the membrane is washed, bound-labeled antibody is detected with a photometric or chemiluminescent detection system.

QUANTITATIVE METHODS

Immunochemical techniques have been used to develop quantitative methods and include turbidimetric and nephelometric assays and labeled immunochemical assays.

Turbidimetric and Nephelometric Assays

Turbidimetry and nephelometry are convenient techniques, based on turbidity and light scattering, respectively, that are used to measure the rate of formation of immune complexes in vitro. Instrumental principles for these methods are described in [Chapter 9](#). Studies have shown that the reaction between antigen and antibody begins within milliseconds and continues for hours. The performance of both types of assays has been improved significantly by increases in the reaction rate attained by the addition of water-soluble linear polymers.

Both turbidimetric and nephelometric immunochemical methods using rate and pseudoequilibrium protocols have been described for (1) proteins, (2) antigens, and (3) haptens. In rate assays, measurements are made early in the reaction because the largest change (dI_s/dt) in intensity of scattered light (I_s) with respect to time is attained during this time interval. For pseudoequilibrium assays, waiting 30 to 60 minutes is necessary so that the dI_s/dt is small relative to the time required to make the necessary measurements. Such assays are termed *pseudoequilibrium* rather than *equilibrium* because true equilibrium is not reached within the time allowed for these assays.

Nephelometric methods are generally more sensitive than turbidimetric assays and have a lower limit of detection of approximately 1 to 10 mg/L for a serum protein. Lower limits of detection are attained in fluids such as cerebrospinal fluid and urine because of their lower lipid and protein concentrations, which result in a higher signal-to-noise ratio. In addition, for low-molecular-weight proteins such as myoglobin (MW 17,800 Da), limits of detection have been lowered through a latex-enhanced procedure based on antibody-coated latex beads.

Nephelometric and turbidimetric assays have also been applied to the measurement of drugs (haptens). An example of this type of assay is the particle-enhanced turbidimetric inhibition immunoassay (PETINIA) that measures decreasing agglutination in the presence of increasing concentrations of analyte (e.g., digoxin). The reagents comprise an antibody to the analyte of interest and a reagent containing the analyte of interest linked to a latex bead. In the absence of analyte in a specimen, reagent antibody binds to the reagent containing the analyte linked to the latex bead, resulting in increased

turbidity. When a specimen with high analyte concentrations is added to the reagent mixture, the reagent antibody is bound by the analyte in the specimen and not to the reagent containing the analyte linked to the latex bead. Thus the presence of specimen analyte results in less turbidity.

Surface Plasmon Resonance–based Immunoassay

Surface plasmon resonance (SPR) is a label-free immunoassay based on an optical phenomenon that enables detection of unlabeled reactants in real time based on changes in the index of refraction at the surface where the binding interaction occurs. The assay is conducted on an electrically conducting gold-coated glass slide mounted on a prism. The binding agent is immobilized on the gold surface over which reactant is flowed. Polarized light is directed underneath the glass slide and interacts with the gold surface to produce electron charge density waves called plasmons at the sample and gold surface interface. This results in a reduction in the intensity of the reflected light. Slight changes in the refractive index at the interface lead to a change in the signal, thus facilitating real-time detection of surface molecular interactions (e.g., association and dissociation of biomolecules with the binder immobilized on the gold surface). SPR assays are used to characterize binding reactions (e.g., antibody affinity, kinetics, cross-reactivity).

Labeled Immunochemical Assays

The previously discussed methods rely on examination of immune complex formation as an index of antigen-antibody reaction. As demonstrated in [Eq. 15.1](#), the overall reaction occurs in sequential phases, and only the final phase consists of formation of the immune complex. However, initial binding of antibody and antigen has been used with antigens and antibodies that have **labels** to develop many sensitive and specific immunochemical assays. The reaction describing this initial binding and the kinetic constant for the overall reaction are shown in [Eqs. 15.2a and 15.2b](#), respectively.

$$K = \frac{[\text{AbAg}]}{[\text{Ab}][\text{Ag}]} \quad (15.2b)$$

where k_1 = rate constant for the forward reaction; k_{-1} = rate constant for the reverse reaction; and K = equilibrium constant for the overall reaction.

As predicted from the law of mass action, the concentrations of Ab, Ag, and Ab:Ag are dependent on the magnitude of k_1 and k_{-1} . For polyclonal antiserum, the average avidity of the antibody populations determines K , and the magnitude of k_1 in comparison with k_{-1} determines the ultimate limit of detection attainable with a given antibody population.

Types of Labels

In the decade following the pioneering developments of Yalow and Berson in 1960, all immunoassays used radioactive **labels** in competitive assays. Since the introduction of enzyme

with the bound antigen through a second and distinct epitope. After additional washing to remove the excess unbound labeled antibody, the bound label is measured, and its concentration or activity is directly proportional to the concentration of antigen.

In noncompetitive assays, either polyclonal or monoclonal antibodies are used as capture and labeled antibodies. If monoclonal antibodies with specificity for distinct epitopes are used, simultaneous incubation of the sample and the conjugate with the capture antibody is possible, thus simplifying the assay protocol.

Noncompetitive immunoassays are performed in simultaneous or sequential mode. In the simultaneous mode, a high concentration of analyte saturates both capture and labeled antibodies. Under these conditions, the analyte is present in such high concentrations that it reacts simultaneously with the capture and labeled antibodies, reducing the number of complexes formed and producing a falsely low result. Thus the calibration curve of the assay exhibits a **hook effect**, in which the assay response drops off at high analyte concentrations in assays for analytes for which the normal pathologic concentration range is very wide. For example, assays for chorionic gonadotropin (CG) and alpha fetoprotein (AFP) are particularly prone to this problem. Dilutions of a sample usually are reanalyzed to check for this type of analytical interference. In practice, the hook effect is eliminated if a sequential assay format is adopted and the concentrations of capture and labeled antibody are sufficiently high to cover analyte concentrations over the entire analytical range of the assay.

Noncompetitive immunoassays rely on different epitopes on a large analyte molecule so as to provide a binding site for both the capture antibody and for the labeled antibody. In the past, a small molecule could not be measured using the conventional sandwich format because a small molecule had too few epitopes. One strategy developed to expand the scope of the sandwich assay to small molecules is exemplified by a 25-hydroxy vitamin D (25OH-D) assay. In this assay format, 25OH-D binds to an immobilized capture antibody and a second antibody (an antimetatype antibody) specifically recognizes the immunocomplex formed between the 25OH-D molecule and the capture antibody, hence facilitating a sandwich assay design.

Heterogeneous Versus Homogeneous Immunochemical Assays

Immunochemical assays that require separation of the free from the bound label are termed **heterogeneous immunoassays**. These assays use labeled antigen where the measurable property of the label is the same, whether it is bound to antibody or not; thus bound and free label must be physically separated to measure how much is bound to antibody. **Homogeneous immunoassays** do not require separation because the measurable property of the label depends on whether it is bound to antibody or not.

Heterogeneous immunoassays. Heterogeneous immunoassays implicitly assume that $k_1 \gg k_{-1}$, and solid phase adsorption is widely used to separate the free, labeled (Ag:L) from the bound, labeled antigen (Ag:L:Ab).

Solid phase adsorption is the separation technique that currently is the most popular and widely used in both manual and automated heterogeneous immunoassays. In this technique, the binding and competition of labeled and unlabeled antigens for the binding sites of the antibody occur on the surface of a solid support onto which the capture antibody has been attached by physical adsorption or covalent bonding. Several different types of solid supports have been used, including the inner surface of plastic tubes or wells of microtiter plates, and the outer surface of insoluble materials such as cellulose or magnetic latex beads or particles. With tubes and microtiter plates, the solid surface containing the attached antibody and the bound antigen is washed “in place,” and indicator reagents are subsequently added to complete the assay. When beads or particles are used, they are added directly to the reaction mixture and, after incubation, are removed by centrifugation or magnetic separation. After the supernatant has been removed by siphoning or decanting, the beads or particles are washed and indicator reagents subsequently added to complete the assay.

Homogeneous immunoassays. Homogeneous immunoassays do not require separation of bound and free labeled antibody or antigen. In this type of assay, the activity of the label attached to the antigen is modulated directly by antibody binding. The magnitude of the modulation is proportional to the concentration of the antigen or antibody being measured. Consequently, it is necessary only to incubate the sample containing the analyte antigen with the labeled antigen and antibody and then directly measure the activity of the label “in place,” making these assays technically easier and faster (see Points to Remember box).

POINTS TO REMEMBER

Important nonseparation (homogeneous) immunoassays include:

- Enzyme-multiplied immunoassay technique (EMIT)
- Cloned enzyme donor immunoassay (CEDIA)
- Luminescent oxygen channeling immunoassay (LOCI)
- Fluorescence resonance energy transfer (FRET)

Homogeneous immunoassays that use enzyme labels that are performed on spectrophotometric analyzers (see subsequent descriptions of the enzyme multiplied immunoassay technique [EMIT] and the cloned enzyme donor immunoassay [CEDIA]) are in routine use for a range of small molecules. A homogeneous sandwich format chemiluminescent immunoassay has also been developed that expands the scope of homogeneous assays to large molecules (see subsequent description of the luminescent oxygen channeling immunoassay [LOCI]). In addition, a diverse range of homogeneous fluoroimmunoassays (FIAs) based on fluorescence resonance energy transfer (FRET) between fluorescent donor dye- and fluorescent acceptor dye-labeled assay components represent a further expansion of the scope of homogeneous immunoassays (see subsequent descriptions of FRET).

Immunoassay Calibration

Calibration of an immunoassay involves assaying a series of calibrators with known values and fitting a straight line or curve to the resulting data to determine the relationship between the measurable signal and the analyte concentration. This dose-response curve is then used to determine the concentration of analyte in the patients' samples. Joining successive points in a calibration curve is usually achieved by means of an appropriate mathematical equation. Several curve-fitting methods are in use. Interpolation methods join successive points by straight lines (linear interpolation) or curved lines (curvilinear interpolation). When the latter approach is used, a cubic polynomial ($y = a + bx + cx^2 + dx^3$) links the response (y) to the calibrator concentration (x), and the best fit is attained through a series of recalculations (iterations) that smooth the joints between the curves linking successive points on the curve. The resulting equation is called a *spline function*. Empirical curve-fitting methods use different mathematical models, including (1) hyperbolic, (2) polynomial, and (3) log-logit and its variants (e.g., four-parameter log-logistic), to calculate a curve to fit the calibration data.

It should be appreciated that a source of error with all curve-fitting methods is the uncertainty of the shape of the curve between successive calibrators and the imprecision in the measurement of each calibrator. Imprecision may not be constant over the concentration range represented by the calibrators, and in this case the response variable is termed *heteroscedastic*.

Analytical and Functional Sensitivity

The analytical limits of detection of **competitive immunoassays** are determined principally by the affinity of the antibody. A lower limit of detection of 10 fmol/L (i.e., 600,000 molecules of analyte in a typical sample volume of 100 μ L) is possible in a competitive assay when an antibody with an affinity of 10^{12} mol/L is used.

For noncompetitive immunoassays, the ability of the detector to measure the label determines the detection limit of an assay. A radioactive label, such as ^{125}I , has low specific activity (7.5 million labels necessary for detection of 1 disintegration/s) compared with enzyme labels and chemiluminescent and fluorescent labels. Enzyme labels provide an amplification (each enzyme label producing many detectable product molecules), and the detection limit for an enzyme is lowered if the conventional photometric detection is replaced with chemiluminescent or bioluminescent detection. The combination of amplification and an ultrasensitive detection reaction makes noncompetitive chemiluminescent EIAs among the most sensitive types of immunoassays. Fluorescent labels also have high specific activity; a single high-quantum-yield fluorophore is capable of producing 100 million photons/s. In practice, several factors degrade the detection limit of an immunoassay. These include (1) background signal from the detector, (2) assay reagents, and (3) nonspecific binding of the labeled reagent.

Secondary labels such as biotin are used to introduce amplification into an immunoassay. The binding constant

of the biotin/avidin complex is extremely high (10^{15} mol/L). This high binding allows for the design of immunoassay systems that are even more sensitive than the simple antibody systems. Such a biotin/avidin system uses a biotin-labeled first antibody. Biotin is attached to the antibody in relatively high proportion without loss of immunoreactivity of the antibody. When an avidin-conjugated label is added, a complex of Ag:Ab-biotin:avidin label is formed. Further amplification is achieved by a biotin:avidin:biotin linkage because the binding ratio of biotin:avidin is 4:1 (e.g., Ag:Ab-biotin:avidin:[3 biotin labels]). If the label is an enzyme, large numbers of enzyme molecules in the complete complex provide a large increase in enzymatic activity, coupled with the small amount of antigen being determined, and the antigen assay is correspondingly more sensitive.

Another type of sensitivity is termed "functional sensitivity." This is defined as the lowest concentration that can be measured in an assay with an interassay coefficient of variation of 20% (see also [Chapter 2](#)). This is used to establish a more realistic and robust detection limit for an assay used in patient care. Functional sensitivity is associated with the concept of assay generations, each successive generation representing a one-log concentration improvement in sensitivity (e.g., for a thyroid-stimulating hormone [TSH] immunoassay first generation 1 mIU/L, second generation 0.1 mIU/L, etc.).

Examples of Labeled Immunoassays

Specific examples of different types of labeled immunoassays are discussed in the following section.

Radioimmunoassay. Radioimmunoassays (RIAs) use radioactive isotopes of iodine, ^{125}I and ^{131}I , and tritium (^3H) as labels. In practice, competition between radiolabeled and unlabeled antigen or antibody in an antigen-antibody reaction is used to analytically determine the concentration of the unlabeled antigen or antibody. It takes advantage of the specificity of the antigen-antibody interaction and the ability to measure very low quantities of radioactive elements. RIAs have been used to determine the concentration of antibodies or any antigen against which a specific antibody is produced. When used to measure the concentration of an antigen, RIA requires that the antigen be available in a pure form and be labeled with a radioactive isotope. An alternative assay design uses labeled antibody (e.g., immunoradiometric assay [IRMA]) and does not require purified antigen because the antigen need not be labeled. This obviates potential problems that may be caused by iodination of labile antigens. Antibodies are more stable proteins and are easier to label without damage to the function of the protein.

Nonseparation RIAs have also been developed that are based on the modulation of a tritium or ^{125}I label by microparticles loaded with a scintillant. These scintillation proximity assays (SPAs) have found routine application in high-throughput screening assays for drug discovery.

Although they were once popular, the use of RIAs in clinical laboratories has declined primarily because of concerns over safe handling and disposal of radioactive reagents and waste.

Enzyme immunoassay. EIAs use the catalytic properties of enzymes to detect labeled antigens or antibodies, discriminate between bound and free label, and quantify immunological reactions. Alkaline phosphatase (ALP), horseradish peroxidase (HRP), glucose-6-phosphate dehydrogenase (G6PDH), and β -galactosidase labels predominate in EIA.

Various detection systems have been used to monitor and quantify EIAs. Assays that produce compounds that can be monitored photometrically are very popular because compact, high-performance photometers are available. However, EIAs that use fluorescent- or chemiluminescent-labeled substrates or products are often preferred to photometry-based assays, owing to the inherent sensitivity of fluorescent and chemiluminescent measurements. Immunoassays that incorporate HRP as a label can be assayed by chemiluminescence using a mixture of luminol, peroxide, and an enhancer such as *p*-iodophenol (Fig. 15.7A), or by using an acridan derivative. A very sensitive assay for ALP labels uses a chemiluminescent adamantyl 1,2-dioxetane aryl phosphate substrate (see Fig. 15.7B). The enzyme dephosphorylates the substrate, which decomposes with a concomitant long-lived glow of light (detection limit for ALP using this assay is 10 zeptomoles [10^{-20} moles]).

Types of EIA include (1) enzyme-linked immunosorbent assay (ELISA), (2) EMIT, and (3) CEDIA.

Enzyme-linked immunosorbent assay. ELISA is a heterogeneous EIA technique. With this type of assay, one of the reaction components is attached to the surface of a solid phase, such as that of a microtiter well. This attachment may consist of nonspecific adsorption or chemical or immunochemical bonding and facilitates separation of bound and free labeled reactants. Typically with ELISA, an aliquot of sample or calibrator containing the antigen to be measured is added to and allowed to bind with a solid phase antibody.

Fig. 15.7 Ultrasensitive assays using horseradish peroxidase and alkaline phosphatase labels. (A) Chemiluminescent assay for horseradish peroxidase label using luminol. (B) Chemiluminescent assay for an alkaline phosphatase label using AMPPD (disodium 3-(4-methoxyspiro[1,2-dioxetane-3,2'-tricyclo[3.3.1.1]decan-4-yl]phenyl)phosphate).

After the solid phase has been washed, an enzyme-labeled antibody different from the bound antibody is added and forms a “sandwich complex” of solid phase–Ab:Ag:Ab enzyme. Excess (unbound) antibody then is washed away, and enzyme substrate is added. The enzyme label then catalyzes the conversion of substrate to product(s), the amount of which is proportional to the quantity of antigen in the sample. Antibodies in a sample also are quantified through the use of an ELISA procedure in which antigen instead of antibody is bound to a solid phase, and the second reagent is an enzyme-labeled antibody specific for the analyte antibody. For example, in a microtiter plate format, ELISA assays have been used extensively for detection of antibodies to viruses and parasites in serum or whole blood. In addition, enzyme conjugates coupled with substrates that produce visible products have been used to develop ELISA-type assays with results that are interpreted visually.

Enzyme-multiplied immunoassay technique. EMIT is a homogeneous EIA that is very widely used in clinical analyses, an illustration of which is shown in Fig. 15.8. Because EMIT does not require a separation step, it is simple to perform and has been used to develop a wide variety of small molecule (drug, hormone, or metabolite) assays. Because of their operational simplicity, EMIT-type assays are easily automated and are included in the repertoire of many automated clinical and immunoassay analyzers. In this technique the patient's sample is incubated with (1) an enzyme conjugated to the antigen (drug, hormone, or metabolite), (2) antibody against the antigen, and (3) the enzyme substrate. Antigen in the patient's sample competes with the enzyme-conjugated antigen for the antibody. Binding of the antibody to the enzyme-antigen conjugate affects enzyme activity by physically blocking access of the substrate to the active site of the enzyme or by changing the conformation of the enzyme molecule and thus altering its activity. The relative change in enzyme activity resulting

Fig. 15.8 Enzyme-multiplied immunoassay technique (EMIT) and cloned enzyme donor homogeneous immunoassay (CEDIA). Ab, Antibody; Ag, antigen; EA, enzyme acceptor; EA:Ag, antigen labeled enzyme acceptor; (EA:ED:Ag)₄, enzymatically active tetrameric β -galactosidase; ED, enzyme donor.

from the formation of the antigen-antibody complex is proportional to the antigen concentration in the patient's sample. Concentration of the antigen is calculated from a calibration curve prepared by analyzing calibrators that contain known quantities of the antigen in question.

Cloned enzyme donor immunoassay. As shown in Fig. 15.8, CEDIA is a homogeneous EIA; it was the first EIA designed and developed through the use of genetic engineering techniques. Two inactive fragments (the enzyme “donor” and “acceptor”) of β -galactosidase are prepared by manipulation of the Z gene of the *lac* operon of *Escherichia coli*. These two fragments spontaneously reassemble to form active enzyme even if the enzyme donor is attached to an antigen. However, binding of antibody to the enzyme donor-antigen conjugate inhibits reassembly, and no active enzyme is formed. Thus competition between the antigen and the enzyme donor-antigen conjugate for a fixed amount of antibody in the presence of the enzyme acceptor modulates the measured enzyme activity. High concentrations of the antigen result in the greatest enzyme activity; low concentrations result in the least enzyme activity.

Fluoroimmunoassay. Fluoroimmunoassay (FIA) uses a fluorescent molecule as an indicator label to detect and quantify immunologic reactions. Examples of fluorophores used as labels in FIA and their properties are listed in Table 15.2. An early problem with FIA was that background fluorescence from within the sample limited its utility. This problem has been overcome by the use of time-resolved immunoassay techniques that use chelates of rare earth (lanthanide) elements as labels (see Chapter 9). These techniques are based on the fact that fluorescent emissions from lanthanide chelates such as (1) europium, (2) terbium, and (3) samarium have long lives ($>1 \mu\text{s}$) compared with the typical background fluorescence encountered in biologic specimens. In a time-resolved FIA, a europium chelate label is excited by a pulse of excitation light ($0.5 \mu\text{s}$), and the long-lived fluorescence

emission from the label is measured after a delay (400 to $800 \mu\text{s}$). The measurement after the delay ensures that any short-lived background signal has decayed.

Fluorescence polarization immunoassay (FPIA) is a type of homogeneous FIA that is widely used to measure drugs and other small molecules (Fig. 15.9). The polarization of the fluorescence from a fluorescein-antigen conjugate is determined by its rate of rotation during the lifetime of the excited state in solution. When the fluorescein-antigen conjugate is bound to the large antibody molecule, the fluorophore is constrained from rotating in the time between absorption of the incident radiation and emission of fluorescence; hence the fluorescence emission is still highly polarized. In contrast, when the fluorescein-antigen conjugate is free in solution, it can rotate more rapidly and the emitted light is depolarized. Thus binding to antibody modulates polarization, and a homogeneous assay is possible.

Förster or FRET is the distance-dependent transfer of energy from a fluorescent donor dye to a fluorescent acceptor dye. Distances at which there is 50% transfer efficiency are typically 1 to 20 nm, and up to approximately 20 nm is possible for some donor-acceptor pairs (e.g., lanthanide chelates and quantum dots). In, for example, a sandwich FRET immunoassay format used in the time-resolved amplified cryptate emission (TRACE) assay, an antibody labeled with a europium chelate (donor) is matched with an antibody labeled with an allophycocyanin dye (XL665; acceptor). The two antibodies form a sandwich immunocomplex with the antigen, and following irradiation with a pulsed excitation light (337 nm), energy transfer occurs from the donor europium chelate to the XL665 acceptor. In the absence of immunocomplex formation, the XL665 fluorescence is short-lived (nanoseconds). However, with immunocomplex formation, the europium chelate on the first antibody provides sustained energy to excite and prolong the normally short-lived fluorescence of the XL665 dye on the second antibody (microseconds).

TABLE 15.2 Properties of Fluorescent Labels

Fluorophore	Excitation, nm	Emission, nm	Fluorescence Quantum Yield ^a	Lifetime, ns
Cy3 (cyanine dye)	550	570	0.15	—
Cy5 (cyanine dye)	650	670	0.28	—
Europium (β -naphthoyl trifluoroacetone)	340	590,613	—	500,000
Fluorescein isothiocyanate	492	520	0.0–0.85	4.5

Umbelliferone	380	450	—	—

^aFluorescence quantum yield: fraction of molecules that emit a photon.

Fig. 15.9 Homogeneous polarization fluoroimmunoassay. Ab, Antibody; Ag, antigen; F, fluorescein.

Intensity of the 665-nm emission is proportional to antigen concentration. Another strategy used in a system for cardiac markers uses an antibody-coated latex particle containing a donor dye (a silicon phthalocyanine derivative) and a second antibody-coated latex particle containing an acceptor dye (a different silicon phthalocyanine dye). Analyte in the sample binds to create donor particle:analyte:acceptor particle complexes. Excitation at 670 nm excites the donor dye, and energy transfer to the acceptor dye occurs due to the proximity of the two differently dyed particles. The acceptor particle then emits light at 760 nm (long wavelength in the red portion of the spectrum). An advantage of this red emission is that scattering and fluorescence from blood plasma is minimized.

Phosphor immunoassay. A phosphor is a material that emits light (phosphorescence) over a relatively long time scale following exposure to excitation energy. A particular type of phosphor, an upconverting phosphor nanoparticle, can be used as a label in immunoassays (e.g., to label an antibody in a sandwich immunoassay). In one application, the upconverting phosphor nanoparticle (200- to 400-nm diameter) can be a crystalline lanthanide oxysulfide. This nanoparticle absorbs two or more photons of infrared light (980 nm) and produces light emission at a shorter wavelength (anti-Stokes shift). The phosphorescence is not influenced by reaction conditions (e.g., temperature, buffer), and no upconverted signal is obtained from biologic components in the sample (low background). Multiplexing is possible because different types of particles produce different wavelengths of phosphorescence (e.g., yttrium/erbium oxysulfides are green [550 nm], yttrium/thulium oxysulfide particles are blue [475 nm]).

Chemiluminescent immunoassay. Chemiluminescence is the name given to light emission produced during a chemical reaction. Isoluminol and acridinium esters are important examples of chemiluminescent labels used in chemiluminescent immunoassays. Oxidation of isoluminol by hydrogen peroxide in the presence of a catalyst, such as microperoxidase, produces a relatively long-lived light emission at 425 nm, and oxidation of an acridinium ester by alkaline hydrogen peroxide in the presence of a detergent (e.g., Triton X-100) produces a rapid flash of light at 429 nm. Acridinium and sulfonyl acridinium esters are high specific activity labels (detection limit for the label is 800 zeptomoles) that can be used to label both antibodies and haptens (Fig. 15.10A).

LOCI is a particularly important type of chemiluminescent immunoassay. It is one of the few homogeneous immunoassays that operate in a noncompetitive (“sandwich”) format and can be used to assay large molecules. LOCI uses two reagent particles (sensitizer and chemiluminescer particles) that form a complex with the analyte of interest. The presence of analyte links the two reagent latex particles in close proximity. The first particle contains a photosensitizer (e.g., phthalocyanine) and, in the presence of light, converts oxygen to singlet oxygen. The second chemiluminescer particle contains a chemiluminescent agent (e.g., olefin) that reacts with singlet oxygen to form a dioxetane that decomposes and emits light. This reaction occurs only if the two particles are in close proximity and the singlet oxygen can diffuse

efficiently from the sensitizer particle to the chemiluminescer particle. Singlet oxygen does not react with unbound chemiluminescer particles because of the short lifetime of this transient species in an aqueous environment. An example of a LOCI assay for TSH is illustrated in Fig. 15.11. TSH binds to a biotinylated anti-TSH antibody, and this complex links

Fig. 15.10 Luminescent labels. (A) Chemiluminescent acridinium ester label. (B) Electrochemiluminescent ruthenium (II) tris(bipyridyl) NHS (*N*-hydroxysuccinimide) ester label. Novel poly-substituted aryl acridinium esters and their use in immunoassay. *Journal of Bioluminescence and Chemiluminescence*, 4, 88–98.)

Fig. 15.11 Example of luminescent oxygen channeling immunoassay for thyroid-stimulating hormone (TSH). In this assay, TSH links two latex microbeads—one containing a photosensitive reagent and the other, a precursor of a chemiluminescent reagent. *b*, Biotin; SAV, streptavidin; UV, ultraviolet.

the streptavidin-coated sensitizer particle to the anti-TSH antibody-coated chemiluminescer particle. Exposure of light results in emission of singlet oxygen from the photosensitive particle. The singlet oxygen activates the chemiluminescent particle to emit light that is then measured.

Electrochemiluminescence immunoassay. Ruthenium (II) tris(bipyridyl) (see Fig. 15.10B) undergoes an electrochemiluminescent reaction (620 nm) with tripropylamine at an electrode surface, and this chelate is now used as a label in competitive and sandwich electrochemiluminescence immunoassays. Using this label, various assays have been developed with magnetic beads as the solid phase. Beads are captured by a magnet at an electrode surface in a flow cell, and unbound label is washed out of the cell by a wash buffer. Label bound to the bead undergoes an electrochemiluminescent reaction, and the light emission is measured by an adjacent photomultiplier tube.

Particle immunoassay. Various micro- and nano-sized particles can be used as labels. For example, dyed-latex particles and gold sols are visible to the naked eye and have found wide application in simplified immunoassays based on the lateral flow principle (Chapter 17). A magnetic particle, detected via its reflective and light scattering properties, is used in an optomagnetic sandwich immunoassay. Magnetic nanoparticles coated with detection antibody bind to captured antigens and are detected using frustrated total internal reflection. An advantage of this assay format is speed (external fields are used to manipulate the magnetic particles), and it has been applied to a fast turnaround intraoperative parathyroid hormone assay.

Nuclear magnetic resonance detection of magnetic particle labels facilitates a homogeneous immunoassay design. The assay uses magnetic nanoparticles (~20-nm diameter) coated with antibody that binds to and clusters around analyte in solution. A consequence of the binding and clustering is that the microscopic environment of water in the reaction mixture is altered, and this can be detected by nuclear magnetic resonance as a change in the T2 relaxation signal (Fig. 15.12). An advantage of this type of immunoassay is that the signal

is unaffected by the sample matrix (e.g., opacity), and this allows direct detection in various types of specimens (e.g., whole blood and sputum).

Immuno-polymerase chain reaction and bio-barcode immunoassay. DNA has been used in a number of different immunoassay designs. Immuno-PCR is a heterogeneous immunoassay in which a piece of single- or double-stranded DNA is used as a label for an antibody in a sandwich assay. Bound DNA label is amplified using the polymerase chain reaction (PCR). The amplified DNA product is separated by gel electrophoresis and quantitated by densitometric scanning of an ethidium-stained gel.

In a bio-barcode assay, capture antibody immobilized on a magnetic particle binds to the analyte (e.g., a protein) and the bound analyte is reacted with a gold particle (30-nm diameter) decorated with detection antibody and barcode dsDNA (Fig. 15.13; refer to the figure legend for details). Following complex formation and washing, one strand of the barcode dsDNA is released from the gold particle. Next, the released barcode dsDNA is hybridized to an immobilized capture DNA probe and to a gold particle-labeled detection probe. The bound gold particle-labeled detection probe is first decorated with silver and then detected scanometrically. This type of assay has achieved very low detection limits (e.g., pg/mL range for serum prostate-specific antigen).

Multiplexed immunoassays and protein microarrays. Multiplexed immunoassays, in which two or more analytes are detected/measured in a single assay, improve the efficiency of detecting/measuring multiple analytes. Two important strategies are based on discrete reaction zones on a planar surface (microarray) and on optically coded microspheres ("liquid array").

Arrays of hundreds or thousands of micrometer-sized dots of antigens or antibodies immobilized on the surface of a glass or plastic chip are emerging as an important tool in proteomic studies and in assessing protein-protein interactions. This format facilitates simultaneous multianalyte immunoassays using (e.g., fluorophore-labeled conjugates). The arrays

Fig. 15.12 Magnetic particle immunoassay. Antigen binds to magnetic nanoparticles (~20-nm diameter) coated with antibody. The binding and resulting clustering of the particles alters the microscopic environment of water in the reaction mixture and this can be detected by nuclear magnetic resonance (change in the T2 relaxation signal).

Fig. 15.13 Bio-barcode assay for a protein target. Barcode DNA-functionalized gold nanoparticles (Au-NP) (30-nm diameter) are conjugated to target protein-specific antibodies (via tosyl [Ts] groups) to generate the coloaded target protein Au-NP probes that are then passivated with bovine serum albumin (BSA). The next steps in the sandwich immunoassay are reaction of the target protein with 1- μ m magnetic microparticle probes (MMPs) coated with monoclonal antibodies to target protein, washing to remove excess serum components, and then reaction with the Au-NP. After magnetic separation and wash steps, the target protein-specific DNA barcodes are released into solution and detected using the scanometric assay (includes a Au-NP-catalyzed silver enhancement step). Approximately one-half of the barcode DNA sequence (green) is complementary to the “universal” scanometric Au-NP probe DNA, and the other half (purple) is complementary to a surface immobilized DNA sequence that is responsible for sorting and binding barcodes complementary to the target protein barcode sequence. (From Thaxton, C. S., Elghanian, R., Thomas, A. D., Stoeva, S. I., Lee, J.-S., Smith, N. D., et al. [2009]. Nanoparticle-based bio-barcode assay redefines “undetectable” PSA and biochemical recurrence after radical prostatectomy. *Proceedings of the National Academy of Sciences of the United States of America*, 106, 18437–18442, with permission.)

are made by printing or spotting 1-nL drops of protein solutions onto a flat surface, such as a glass microscope slide. In a typical sandwich assay, the array on the surface of the slide is incubated with sample and then with conjugate. The fluorescence of the bound conjugate is detected using a scanning device. The pattern of the signal provides information on the presence and amount of individual analytes in the sample or the reactivity of a single analyte with the range of proteins arrayed on the surface of the slide.

Another type of microarray, the so-called liquid array, is based on collections of microbeads optically coded with fluorescent dyes. Each type of fluorescent bead is coated with a different antibody and following the immunologic reaction with sample and labeled antibody, the formation of an immunocomplex on each bead is assessed using flow cytometric or fluorescence imaging principles. Up to 500 different

signatures can be created allowing multiplexing of up to 500 different assays in a single assay vessel.

Digital immunoassay. A long-cherished goal in immunoassay has been single molecule sensitivity. A new digital immunoassay design has led to dramatic improvements in sensitivity (Fig. 15.14). This ELISA type of assay is performed on small antibody-coated paramagnetic microbeads. At the end of the incubation of the capture antibody-coated beads with sample and β -galactosidase labeled antibody, the beads, in the presence of a fluorogenic substrate, are distributed into an array of 216,000 wells (one bead per well) each with a volume of 40 fL. A single target molecule captured onto the bead in an fL-sized well generates sufficient fluorescence signal for detection. The signal from the array of wells is imaged using a charge coupled device (CCD) camera and the number of fluorescent wells is counted (a digital read-out), thus counting the number of molecules in the sample. At the 10:1 bead-to-molecule ratio used in the assay, the number of beads that carry a labeled immunocomplex follows a Poisson distribution, such that at low protein concentrations each bead will capture one labeled immunocomplex or none. The combination of the sensitive label detection method and the low background achieved by the signal counting leads to protein assays with fg/mL sensitivity.

FIA can also be operated in a digital mode by combining a magnetic microparticle-based sandwich FIA and single-molecule counting technology. It integrates capillary flow, laser-induced fluorescence, and a highly sensitive detection optics module for sample analysis. Upon completion of sandwich formation, the fluorescent dye-labeled detection antibody is released from the captured antigen and is eluted into a very small volume (20 μ L) for counting. Fluorescence detection occurs in a flow system in a very small interrogation space (5 μ m) that is illuminated by a laser. Signals above the background are counted as digital events, and the sum of the digital events is related to the original concentration of the analyte in the sample.

Interferences. Immunologic assays are prone to interferences, in spite of the use of highly specific antibodies for molecular recognition of the analyte. Falsely low results can occur because of the hook effect at high antigen concentrations (see earlier discussion). False-negative or false-positive results are encountered if the sample contains anti-animal immunoglobulin antibodies. For example, in a two-site sandwich assay for human chorionic gonadotropin (hCG) based on mouse antibodies, any human anti-mouse antibodies (HAMAs) present in the specimen will recognize the immobilized mouse capture and mouse conjugate antibodies and will form a complex that is indistinguishable from an immobilized capture antibody:hCG:conjugate complex. This leads to a false-positive result. A false-negative result will be obtained if the HAMAs react with the capture antibody or the conjugate to such an extent that specific antibody binding to hCG is prevented. Many different types of circulating anti-animal immunoglobulin antibodies have been detected (e.g., human anti-goat, human anti-bovine antibodies) and shown to interfere in immunoassays. In practice, this type of interference is minimized by including additives in the immunoassay reagents such as nonimmune serum or IgG from the

Fig 15.14 Design of a digital immunoassay (Simoa). (A) Reaction of the antigen with capture antibody-coated magnetic beads and biotinylated detection antibody. This is then followed by reaction of the bound complex with streptavidin- β -galactosidase conjugate to form single immunocomplexes of the magnetic beads. (B) The beads are loaded into wells, one bead per well, and then treated with a fluorometric substrate for β -galactosidase. (C) Fluorescence from the beads in the array detected by imaging. *ELISA*, Enzyme-linked immunosorbent assay. (Images used with permission of Quanterix Corporation.)

species used to raise the antibodies used in the assay. In practice, this type of interference can sometimes be uncovered by performing dilution studies (nonlinear response) or from changes in values following incubation of the sample in a heterophile blocking tube.

CELL-BASED AND TISSUE-BASED IMMUNOCHEMICAL TECHNIQUES

Other analytical methods of clinical interest that use antibodies include immunocytochemistry and agglutination assays.

In immunocytochemical assays, labeled (e.g., horseradish peroxidase) antibody reagents are used as specific probes for protein and peptide antigens to evaluate single cells or pieces of tissue for their synthetic capability and/or phenotypic identity. In an agglutination method, the visible clumping of particulates, such as cells and latex particles, is used as an indicator of the primary reaction of antigen and antibody.

Hemagglutination, agglutination reactions in which the antigen is located on an erythrocyte, is used in the direct testing of erythrocytes for blood group, Rh, and other antigenic types.

REVIEW QUESTIONS

- What does a strong signal in a microtiter well-based competitive enzyme immunoassay (EIA) for thyroxine signify?
 - A low concentration of thyroxine in the sample
 - A high concentration of thyroxine in the sample
 - Enzyme substrate not added to the well
 - Enzyme inhibitor present in the sample
 - Bound antibody has detached from the surface of the well
- What does a very weak signal in a microtiter well-based sandwich EIA for thyroid-stimulating hormone (TSH) signify?
 - A low concentration of TSH in the sample
 - A high concentration of TSH in the sample
 - A hook effect
 - Effective competition between the conjugate and the TSH for capture antibody
 - Capture antibody saturated with TSH:conjugate complexes
- The energy of interaction of a single antibody-combining site and its corresponding epitope on the antigen is referred to as:
 - sensitivity.
 - specificity.
 - immunogenicity.
 - affinity.
- Which one of the following immunochemical assays requires separation of the free label from the bound labeled substance?
 - Enzyme-multiplied immunoassay technique (EMIT)
 - Enzyme-linked immunosorbent assay (ELISA)
 - Cloned enzyme donor immunoassay (CEDIA)
 - Luminescent oxygen channeling immunoassay (LOCI)
 - Fluorescence polarization immunoassay (FPIA)

5. The addition of a linear polymer such as polyethylene glycol to a mixture of antigen and antibody causes _____ in the rate of immune complex formation and precipitation.
 - a. a decrease
 - b. an increase
 - c. no change
6. Transferring electrophoretically separated proteins into a strip of nylon membrane by electroblotting is the second step in:
 - a. radial immunodiffusion.
 - b. enzyme-linked immunosorbent assay.
 - c. Western blotting.
 - d. immunofixation.
 - e. crossed immunoelectrophoresis.
7. In a two-site antibody-based sandwich immunoassay, the presence of human anti-mouse antibodies produces a false-negative result by:
 - a. binding a mouse immunoglobulin capture antibody and the mouse immunoglobulin conjugate to form a bridge.
 - b. mimicking the specific analyte being assessed.
 - c. binding to the mouse monoclonal capture antibody reagents.
 - d. reacting with one of the assay reagents to prevent formation of the sandwich.
8. Which one of the following immunoassay procedures does not involve the coating of a solid phase with antibody or antigen?
 - a. Enzyme-multiplied immunoassay technique (EMIT)
 - b. Luminescent oxygen channeling immunoassay (LOCI)
 - c. Enzyme-linked immunosorbent assay (ELISA)
 - d. Particle-enhanced turbidimetric inhibition immunoassay (PETINIA)
 - e. Bio-barcode immunoassay
9. The immunoglobulin most often used in immunochemical assays is:
 - a. IgG.
 - b. IgA.
 - c. IgM.
 - d. IgE.
10. Which one of the following statements is false?
 - a. Dyed-latex microparticles are effective labels in simplified immunoassays because they are visible to the naked eye
 - b. Binding of an antigen to an antibody involves van der Waals-London dipole-dipole interaction
 - c. Addition of polymers to an antigen antibody reaction increases the rate of immune complex growth
 - d. The functional sensitivity of an immunoassay is the lowest concentration that can be measured with a within-assay coefficient of variation of 20%
 - e. Fluorescence resonance energy transfer from donor to acceptor dye is distance dependent

Automation

*Charles D. Hawker, Jonathan R. Genzen, Carl T. Wittwer**

OBJECTIVES

1. List four benefits of using automation in the clinical laboratory.
2. State four advantages of using bar-coded labels to identify specimens.
3. List and describe the considerations that must be evaluated when an automated laboratory system is selected.
4. List the problems encountered when automated laboratory processes are used and integrated, including specimen identification, specimen delivery, reagent identification, and the chemical reaction phases.
5. Compare the following analyzer configurations with regard to specimen and reagent handling and processing:
 - Random-access
 - Continuous-flow
 - Sequential
 - Multiple-channel
 - Discrete
 - Single-channel
6. Compare an “open” versus a “closed” automated analyzer with regard to reagent usage.
7. Describe how automation has been applied to polymerase chain reaction (PCR) and deoxyribonucleic acid (DNA) sequencing.
8. Describe the trade-offs between automating complex processes and developing simpler processes that do not require automation.

KEY WORDS AND DEFINITIONS

Automation The process whereby an analytical instrument performs many tests with only minimal involvement of an analyst; also defined as the controlled operation of an apparatus, process, or system by mechanical or electronic devices without human intervention.

Batch analysis Type of analysis in which many specimens are grouped in the same analytical session.

Carryover The transport of a quantity of analyte or reagent from one specimen reaction into and contaminating a subsequent one.

Continuous-flow analysis Type of analysis in which each specimen in a batch passes through the same continuous stream at the same rate and is subjected to the same analytical reactions.

Molecular diagnostics Using the presence, quantity, or sequence of DNA or RNA to identify the nature of an illness.

Multiple-channel analysis Type of analysis in which each specimen is subjected to multiple analytical processes so

that a set of test results is obtained on a single specimen; similar to random-access analysis.

Polymerase chain reaction (PCR) A molecular biology method to amplify a segment of DNA by repeated cycles of primer annealing, polymerase extension, and product denaturation.

Random-access analysis The most common configuration of an automated analyzer, in which analyses are performed on a collection of specimens sequentially and each specimen is analyzed for a different selection of tests.

Real-time PCR A variant of PCR where fluorescence is measured during amplification, allowing quantification of the initial template.

Sequential analysis Type of analysis in which each specimen in a batch enters the analytical process one after another, and each result or set of results emerges in the same order as the specimens are entered.

Single-channel analysis Type of analysis in which each specimen is subjected to a single process so that only

*The authors would like to acknowledge the original contributions of Ernest Maclin, PE; Donald S. Young, MB, PhD; and James C. Boyd, MD, upon which portions of this chapter are based.

results for a single analyte are produced; similar to batch analysis.

Southern blotting A method to identify and measure a specific DNA sequence or genes in a mixed extract, where DNA strands are cut with restriction enzymes, separated by gel electrophoresis, transferred to special filter paper, and hybridized.

The term **automation** has been applied in clinical chemistry to describe the process whereby an analytical instrument performs many tests with only minimal involvement of an analyst. However, the term also applies to the automation of nonanalytical processes (preanalytical and postanalytical) that have become very important to the performance of laboratories over the past two decades. This chapter covers both nonanalytical and analytical automation in clinical laboratories.

The availability of automation systems and automated instruments enables laboratories to process much larger workloads without comparable increases in staff. The evolution of automation in clinical laboratories has paralleled that in the manufacturing industry, progressing from fixed automation, whereby an instrument performs a repetitive task by itself, to programmable automation, which allows the instrument to perform a variety of different tasks. Intelligent automation has also been introduced into some individual instruments or systems to allow them to self-monitor and respond appropriately to changing conditions.

One benefit of automation is a reduction in the variability of results and errors of analysis through the elimination of tasks that are repetitive and monotonous for most individuals. The improved reproducibility gained by automation has led to a significant improvement in the quality of laboratory tests.

Many small laboratories now have consolidated into larger, more efficient entities in response to market trends involving cost reduction. The drive to automate these mega-laboratories has led to new avenues in laboratory automation. No longer is automation simply being used to assist the laboratory technologist in test performance; it now includes (1) processing and transport of specimens, (2) loading of specimens into automated analyzers, (3) assessment of the results of the tests performed, and (4) storage of specimens.

Clinical laboratory automation as we know it today owes much to the pioneering efforts of Masahide Sasaki in Kochi, Japan. Beginning in 1981, Dr. Sasaki trained his medical technologists to assemble conveyor belts, construct electronic boards, and program robots, thus leading to the creation of the world's first automated laboratory. When he first revealed his automated laboratory to Western audiences in 1989, Sasaki demonstrated new possibilities for error reduction, cost containment, and unprecedented turn-around times. This led to many visitors to his laboratory as well as collaborations with diagnostic vendors that brought commercial automation products to clinical laboratories throughout Japan. Much of the automation in our laboratories today traces its lineage to these early automation systems in Japan. Thousands of laboratories

Throughput The number of specimens processed by an analyzer during a given period of time, or the rate at which an analytical system processes specimens.

Workstation An area in the clinical laboratory dedicated to a defined task and containing appropriate laboratory instrumentation to carry out that task.

worldwide now have either total laboratory automation (TLA) systems or automated systems that perform specific functions. Automation continues to grow because it is widely recognized as a principal means of eliminating errors; improving quality; and reducing labor, costs, and turn-around time.

NONANALYTICAL AUTOMATION FOR THE CLINICAL LABORATORY

Significant progress has been made in automating pre- and postanalytical activities and integrating these operations with analytical systems. Preanalytical automated systems range from robotics that perform a single function, such as aliquoting or sorting (also called *task-targeted automation systems*), to more complex **workstations** that perform several preanalytical functions. Several options are also available as modules for TLA systems, which are discussed later in this section on nonanalytical automation.

Preanalytical automation begins with automation of operations in the specimen processing area where specimens are (1) identified, (2) labeled, (3) scheduled for analysis, (4) centrifuged, and (5) sorted. After specimens are processed, they are transported to appropriate workstations in the laboratory, either manually or using conveyors, where they can then be analyzed with minimal or no human intervention. Rules-based expert system software (1) assists with the review of laboratory results by automatically releasing results that have no associated problems and (2) identifies any problematic results to bring to the attention of trained medical technologists. All specimens are catalogued after analysis and stored in a central storage facility, which may include automated storage and retrieval functions. The following sections cover various aspects of nonanalytical processes with descriptions of automation for these activities.

Specimen Identification

Typically, the identifying link (identifier) between the patient and specimen is noted at the patient's bedside. Maintenance of this connection is essential throughout (1) transport of the specimen to the laboratory, (2) subsequent specimen analysis, and (3) preparation of a report. Several technologies are available for automatic identification and data collection purposes (**Box 16.1**). In practice, automatic identification includes only technologies that electronically detect a unique characteristic or unique data string associated with a physical object. For example, identifiers such as (1) serial number, (2) part number, (3) color, (4) manufacturer, (5) patient name, (6) medical record number, and (7) accession number have been used to identify an object or patient through the use of electronic data

processing. In a clinical laboratory, labeling with a bar code has become the technology of choice for purposes of automatic identification.

Labeling

In many laboratory information systems (LISs), electronic entry of a test order in the laboratory or at a nursing station for a uniquely identified patient generates a specimen label bearing a unique laboratory accession number. A record is established that remains incomplete until a result (or a set of results) is entered into the computer against the accession number. The unique label is affixed to the specimen collection container when the specimen is obtained and the patient is properly identified. This may be at the bedside using pre-printed labels carried from the laboratory or using a portable label printer connected wirelessly through the network to the laboratory computer. Many companies now provide these portable bar code labeling systems, and many hospitals are now using them. Proper alignment of the label on a specimen tube is critical for subsequent specimen processing when bar-coded labels are used. The Clinical and Laboratory Standards Institute (CLSI) published a standard in 2011 (*Specimen Labels: Content and Location, Fonts, and Label Orientation*) that was intended to standardize specimen labels in clinical laboratories to reduce errors such as patient misidentifications. The focus of this standard was not the bar code but rather the human-readable content of the label, particularly the location and appearance of the patient name.

After the specimen is labeled at the patient's bedside and patient identification and collection information is provided, the labeled specimen is submitted to the laboratory. It may be accompanied by a requisition form, although wireless systems obviate that need and additionally automate the recording of phlebotomist identification (ID) and the date and time of collection. Arrival of the specimen in the laboratory is recorded by a manual or computerized log-in or accessioning procedure in which it is assigned an accession number.

After accessioning, specimens undergo various technical handling processes. Some automated analyzers sample directly from the original collection tube, simultaneously reading the accession number from the bar code label on the tube; other analyzers require an aliquot of the serum or

plasma from the original tube. For processes requiring physical removal of serum or plasma from the original tube into a secondary tube, secondary labels bearing essential information from the original label must be affixed to any secondary tubes created. Secondary bar code labels, if necessary, may be generated at the time of accessioning or at the time the aliquots are prepared. This aliquoting step has been automated with different systems.

Bar Coding

A major advance in the automation of specimen identification in clinical laboratories is the incorporation of bar coding technology in analytical systems. A bar coding system consists of a bar code printer and a bar code reader, or scanner. In clinical laboratories, one-dimensional or linear bar code systems have historically been used. CLSI published a standard (AUTO02-A) in 2000 and updated it (AUTO02-A2) in 2003, specifying that clinical laboratories should only use the Code 128B symbology on specimen labels. However, as this chapter was in preparation, CLSI was developing a new standard (AUTO14) for the use of two-dimensional bar codes in clinical and anatomic pathology laboratories. Two-dimensional bar codes offer the prospect of encoding more data in smaller formats and having greater reliability than one-dimensional bar codes.

In practice, a bar code label (often generated by the LIS and bearing the sample accession number) is placed onto the specimen container and is subsequently "read" by one or more bar code readers placed at key positions in the analytical sequence. Examples of these key positions are a handheld bar code reader in a laboratory section or built-in bar code readers in a task-targeted automation system, the loading unit for a TLA system, and an automated analyzer. The resultant identifying and ancillary information is then transferred to and processed by the system software. Initiating bar code identification at a patient's bedside ensures greater integrity of the specimen's identity throughout these processes.

Unequivocal positive identification of each specimen is achieved in analyzers with bar code readers. Advantages of the use of bar code labels include the following:

1. Elimination of work lists for the system
2. Avoidance of mistakes made in the placement of tubes in the analyzer or during sampling
3. Avoidance of the need for analysis of specimens in a defined sequence
4. Decrease in identification errors

A best practice to reduce errors caused by bar code misreads is to set the bar code readers on analyzers and automation systems to only read the symbology expected on the specimen labels (e.g., Code 128B). This prevents reading errors in the event that a second bar code of a different symbology might be visible on an underlying label.

Identification Errors

Many opportunities arise for the mismatch of specimens and results. The risks begin at the bedside and are compounded with each processing step a specimen undergoes between

collection from the patient and analysis by the instrument. The risks are particularly great when hand transcription is invoked for accessioning, labeling and relabeling, and creation of load lists. An incorrect accession number, one in which the digits are transposed, or a load list with transposed accession numbers may cause test results to be attributed to the wrong patient. An additional hazard exists when specimens must be inserted into certain positions in the loading zone defined by a load list. Human misreading of the specimen label or the loading list may cause misplacement of specimens, calibrators, or controls. Automatic reading of bar code labels reduces the error rate from 1 in 300 characters (for human entry) to about 1 in 1 million characters barring (1) minor imperfections in printed bar codes, (2) improper bar code scanner resolution, or (3) skewed orientation of bar code labels on containers, all of which can result in read errors.

Specimen Preparation

The clotting of blood in specimen collection tubes, their subsequent centrifugation, and the transfer of serum to secondary tubes require a finite time to complete. If performed manually, the process may result in a delay in the preparation of specimens for analysis. To eliminate the problems associated with specimen preparation, systems are being developed to automate this process.

Use of Whole Blood for Analysis

When whole blood is used in an assay system, specimen preparation time is essentially eliminated. Automated or semiautomated ion-selective electrodes, which measure ion activity in whole blood rather than ion concentration, have been incorporated into automated systems to provide certain test results within minutes of collecting a specimen. This approach now is used commonly for assays of electrolytes and some other common analytes. Another approach involves manual or automated application of whole blood to dry reagent films and visual or instrumental observation of a quantitative change.

Specimen Delivery

Automated methods are often used to deliver specimens to the laboratory instead of more manual methods (e.g., phlebotomist transport, courier service, nurse delivery). Pneumatic tube systems have been used in many hospitals, but mobile robots can also transport specimens and other laboratory supplies within a laboratory or to the laboratory from other locations in the facility.

Pneumatic Tube Systems

Pneumatic tube systems provide rapid specimen transport and are reliable when installed as point-to-point services. However, when switching mechanisms are introduced to allow carriers (the bullet-shaped containers used to hold specimens) to be sent to various locations, mechanical problems may occur and may cause misrouting. In addition, close attention to the design of the pneumatic tube system is necessary to prevent hemolysis of the specimen. Avoidance of

sudden accelerations and decelerations and the use of proper packing material inside the carriers can help to minimize hemolysis.

Mobile Robots

Automated guided vehicles (AGVs), also called mobile robots, have been used successfully to transport laboratory specimens both within a laboratory and outside a central laboratory. They are easily adapted to carry various sizes and shapes of specimen containers and are reprogrammable with changes in laboratory geometry. In addition, in a busy laboratory setting, delivery of specimens to laboratory benches by a mobile robot can be more frequent than human pickup and is cost-effective. Inexpensive models follow a line on the floor, but others have more sophisticated guidance systems. Their limitations include the need to batch specimens for greater efficiency and, in most cases, the requirement for laboratory personnel to place specimens onto or remove specimens from the mobile robot at each stopping place.

Single-Function Workstations

Some laboratories have gained efficiency, improved quality, and lowered turn-around time by implementing an automated system that performs a single task. This automation is also referred to as *task-targeted automation*. Examples of such automation include automated centrifuges, decappers, recappers, aliquotters, and sorters. Such systems began to be developed in the 1990s and early 2000s, when TLA systems were relatively expensive and thought to be affordable only by reference laboratories and the largest hospital laboratories. Today these systems continue to be developed and implemented because they offer affordable solutions for specific customer needs. Box 16.2 lists a number of vendors offering one or more single-function workstations. Fig. 16.1 is an example of a sorter, one of the different types of single-function workstations that are available. However, a laboratory could use a sorter for both preanalytical sorting for different testing areas and postanalytical sorting for archival storage.

Multifunction Workstations (Automated Specimen Processing)

Although the manual operations carried out in a specimen processing area may look simple, considerable complexity underlies them. Consequently, specimen processing has been one of the most difficult areas of the clinical laboratory

to automate. Each specimen passing through a processing area has to undergo a series of operations, including (1) receiving the specimen; (2) inspecting it for appropriateness (labeling, container type, temperature, and quantity of specimen); (3) logging the specimens into the LIS; (4) recording the date and time of collection and phlebotomist ID, if not already entered; (5) labeling the specimen with an accession number; and (6) separating urgent and stat specimens from routine specimens. Also, specimens may have to be sorted for centrifugation and aliquoting and may have to be sorted or otherwise prepared for the appropriate laboratory station.

An example of a standalone specimen processing system is shown in Fig. 16.2. Such systems place processed specimens into racks that must be transported manually to the testing areas, with some exceptions. Some of these systems are approximately the size of a large automated analyzer; others may be slightly larger. They may be a good choice for laboratories (1) with daily workloads of 500 to 1500 specimens, (2) with space limitations, or (3) that desire ease of use with different analyzers from different vendors. Some laboratories may choose to use multiples of such a system based on higher daily volumes or to automate postanalytical archiving in addition to preanalytical specimen processing.

Box 16.3 lists vendors offering multifunction or specimen processing workstations. Although there may be some variation in the functions that are included, these systems will typically (1) receive incoming specimens, (2) sort, (3) decap, (4) aliquot, and (5) label aliquot specimen containers with bar codes. All may be interfaced to the laboratory's LIS. Some systems may also include automated centrifugation. Some of the systems sort into instrument-specific racks for analyzers from a number of different vendors. In addition, some users apply these systems to aliquot and sort reference or "send-out" testing, saving considerable time in locating the original specimens after testing in their own laboratory.

Total Laboratory Automation Systems

Several manufacturers offer integrated or modular automation systems that use conveyor belts to connect preanalytical specimen processing and other functions directly to analyzers. Such systems may also include functions such as postanalytical storage or sorting of specimens or aliquots for referral testing or to be transported to low-volume testing areas. A list of automation vendors offering TLA systems can be found in Box 16.4; Fig. 16.3 illustrates a large TLA system with a variety of connected nonanalytical and analytical modules.

In addition to the nonanalytical functions listed in the preceding section, TLA systems typically add (1) conveyor transport; (2) interfacing to automated analyzers; (3) more sophisticated process control; and, in some cases, (4) specimen storage and retrieval. All systems are of modular design, allowing the customer to choose the modules or features that should be included. Some systems use an open design, which permits

interfaces to analyzers from a variety of vendors, but other systems are of a closed design and are interfaced only to the vendor's own analyzers. To achieve maximum effectiveness of an automation system, process control software should be able to read the specimen's ID bar code and obtain information from the LIS about specimen type and ordered tests. The software should then determine the processes the specimen requires and the exact route or course of action for each specimen. It should be able to (1) calculate the number of aliquots and the proper volume for each specimen depending on the tests requested, (2) route the specimens to preanalytical processing equipment and then to analyzers, (3) recap the specimens after testing, and (4) retain the specimens for automatic recall. The software should be able to monitor analyzers for in-control production status and automatically make decisions if a test is not available. Specimen integrity checking should be automatic; rules-based decisions should monitor specimen quality and make these decisions as appropriate. Finally, most process control software should include "autoverification," which is validation of analyzer results by making rules-based decisions that flag exceptions for technologist review, and "autoretrieval" of specimens for repeat, reflex, and dilution testing. Although most of these systems are restricted to handling specific types of specimen containers, they are capable of processing much of the daily workload of a large clinical laboratory. A few laboratories with workloads of less than 1000 tubes per day have justified these systems because of a shortage of technical help, but typically these systems are designed for laboratories handling 1000 to 25,000 specimens per day. In addition to process control software and an LIS interface, each of these systems incorporates some or all of the following components:

1. *Specimen input area*: This is a holding area where bar code-labeled specimens are introduced into the system.
2. *Bar code reading stations*: Multiple bar code readers are placed at critical locations in the processing system to track specimens and provide information for their proper routing to various stations. Alternately, bar code readers may only be required at limited locations in the system if each transport carrier (puck) has a unique ID such as a radiofrequency identification (RFID) chip, and the specimen's bar code ID is "married" to the puck's ID when first placed in the puck.
3. *Transport system*: Segments of a conveyor belt line that move specimens to the appropriate location.
4. *A high-level device to sort or route specimens*: A device that separates specimens based on processing requirements or order code and passes them to the transport system or to a system using racks. A high-level sorter is often used to separate specimens that require centrifugation or other processing steps from specimens that do not, or to route specimens into completely different pathways within the total automation system.
5. *Automated centrifuge*: An area of the specimen processor in which specimens requiring centrifugation are removed from the conveyor belt, introduced into a centrifuge with automatic balancing, centrifuged (refrigerated or at room temperature), and then placed back on the transport system.
6. *Level detection and evaluation of specimen adequacy (specimen integrity)*: An area where sensors are used to evaluate the volume of specimen in each specimen container and to look for the presence of hemolysis, lipemia, or icterus. Very few TLA systems have such capability outside of automated chemistry analyzers.
7. *Decapper station*: An area or device in the automated system where specimen caps or stoppers are automatically removed and discarded into a waste container.
8. *Recapper station*: An area or device in the automated system where specimen tubes are automatically recapped with new screw caps, stoppers, or other air-tight closures.
9. *Aliquotter*: A machine that aspirates appropriately sized aliquots from each original specimen container and places them into bar-coded secondary specimen containers for sorting and transport to multiple analytical workstations. The process controller generally instructs the aliquotter as to how many aliquots of what volumes are required based on the bar code ID of the specimen.
10. *Interface to automated analyzer*: A direct physical connection to an automated analyzer that permits the analyzer's sampling probe to aspirate directly from an open specimen container while the container is still on the conveyor or that may robotically lift the container from the conveyor and place it onto the analyzer.
11. *Sorter*: An automated sorter to sort specimens not going to a conveyor-interfaced analyzer or workstation. Such a sorter typically sorts into 30 to 100 different sort groups in racks or carriers. In some systems, the racks may be specific to certain analyzers for convenience. The sorter may also serve as a temporary holding area for specimens that may require a repeat test (see take-out stations) or may sort specimens for referral testing.
12. *Take-out stations*: Temporary storage areas for specimens before or after analysis. The take-out station may be the same as the sorter described earlier, where specimens are sorted for manual delivery. However, it may also serve as a holding area (stockyard) for specimens awaiting autoverification of results if a repeat test is required.
13. *Storage and retrieval system*: This unit may serve the same function as the take-out station or stockyard—that of holding specimens after analysis in case a specimen is necessary for a repeat test—but it has one major difference. These units are typically refrigerated and hold many more specimens (3000 to 30,000) than the typical take-out station or stockyard. Depending on daily workloads, the laboratory may be able to retain up to 1 week's worth of specimens for possible repeat or additional tests. Specimen containers are loaded and retrieved with a robot. Some storage systems include automated specimen discard directly into biohazard waste bins after a predetermined storage duration has been reached.

Conveyor Belts

One main feature of integrated TLA systems is the use of conveyor belts. Ordinary industrial conveyor belts have been used successfully when only transportation is required.

However, in the past, when conveyors were integrated with other robotic systems to automate pre- or postanalytical functions, this technology had difficulty handling the large variety of specimen containers found in the clinical laboratory. To increase the variety of specimen containers that are carried on a conveyor belt system, specimens are placed into specially designed carriers that fit on the conveyor belt line. Sometimes known as “pucks” or “racks” (depending on whether they carry individual specimens or groups of specimens), the carriers have receptacles for variously sized tubes, generally ranging from 13 × 75 mm to 16 × 100 mm. The industrial, motor-driven conveyor belts used in typical laboratory automation systems have transport rates of a few hundred pucks per hour up to 2000 per hour.

Two types of conveyor belt systems are typically used as illustrated in Fig. 16.4. Fig. 16.4A depicts a loop conveyor that has a single module for both input of new specimens and removal of completed specimens. The flow around the loop takes specimens to the processing and analytical modules. Specimens may be sampled directly by the analytical instrument while on the conveyor, or a robot attached to the workstation may remove selected specimens from the conveyor for analysis. Fig. 16.4B depicts a unidirectional conveyor in which specimens are loaded at one end of the belt, flow past various processing and analytical modules, and arrive

at the opposite end where they are removed. Depending on the vendor, both of these conveyor types can have bypass lanes that enable specimens not designated to stop at certain modules to bypass them entirely and proceed to other modules. The advantage of this approach is that it does not require specimens to be aliquoted because specimens pass by all workstations where tests are performed. If specimens are robotically removed from their carriers on the line for testing, systems are required that queue empty carriers to return the tubes to the conveyor and to identify which specimen is in each carrier.

Transfer of specimens from the conveyor belt to the laboratory workstation has been implemented in various ways. For example, some manufacturers have equipped their laboratory instruments with devices to move specimen containers from conveyor belt systems onto the analyzers, and others have installed the ability for the analyzer to sample directly from specimen containers remaining on the conveyor. In practice, the automation system requires a device that stops the tube in the exact location required by the analyzer for sample transfer and verifies and transfers the tube's bar code identification to the analyzer. Depending on the particular automation system, specimens for immediate short turn around testing (STAT) may or may not be processed and analyzed at speeds that are faster than if manually handled. Laboratories that are

Fig. 16.4 (A) A depiction of a laboratory automation system using a continuous loop-type conveyor. In this concept, a single module is used for loading of new specimens and unloading of completed specimens. Depending on the needs of the laboratory, all other modules illustrated are options that can be included or not. (B) A depiction of a laboratory automation system using a unidirectional conveyor. In this concept, separate modules are required for loading of new specimens and unloading of completed specimens. The output module may also perform sorting of specimens for other testing. Other modules can be included, depending on the laboratory's needs.

purchasing laboratory automation systems are advised to learn how each system being considered handles STAT specimens.

Automated Specimen Storage and Retrieval

The automated capability to store and retrieve specimens on demand and with readily known exact storage locations is an important aspect of automated specimen delivery systems. In addition to automated storage and retrieval options in some of the integrated systems described earlier, several automated or semiautomated options for storage and retrieval, as well as LIS modules and PC-based software systems, permit laboratories to track trays or racks of specimens in their own freezers or refrigerators. Some large reference laboratories have adapted large storage systems commonly used in other industries to their laboratory settings.

PRACTICAL CONSIDERATIONS

In this section, the practical considerations that influence a laboratory's decision to automate part or all of its operations are discussed. Some of the suggested readings provide more insights and details about these practical considerations, including workflow mapping.

Evaluation of Requirements

Any consideration of total or modular laboratory automation should start with an evaluation of requirements. Such an evaluation begins with mapping of the current laboratory workflow from the arrival of patient specimens through completion of testing and reporting of results. Box 16.5 lists potential workflow steps that should be mapped. Mapping of material (specimen) flows and data flows is directly related to process flow and assists the laboratory in determining process steps that (1) are bottlenecks, (2) waste labor, and (3) are prone to error. Workflow mapping thus enables the laboratory to better identify what steps should be considered for automation.

Some laboratorians use an "80% rule" in guiding decisions about automation. Clinical laboratories have many exceptional tests, specimen containers, and handling situations. Nevertheless, if 80% of the daily workload of specimen containers, covering most routine handling situations, can be standardized and automated, the laboratory should achieve a significant reduction in its labor usage and costs, sufficient to justify the investment in automation and the planning and evaluation time involved.

After the laboratory's existing workflow is mapped and its requirements are identified, alternative solutions are considered. Use of process improvement techniques such as LEAN and Six Sigma can help to ensure that automated solutions ultimately improve operations. Vendors are invited to make presentations and to host visits of the laboratory management team to other laboratories where vendors have successful installations. It is important at this stage to focus on the requirements identified by workflow mapping and not to allow the vendor to try to sell equipment that may not be necessary. Key points to remember when a laboratory is considering either new automation or an addition to existing automation are listed in the following Points to Remember box.

BOX 16.5 Clinical Laboratory Steps for Workflow Mapping

- Unpacking from transport containers
- Presorting
- Temperature preservation
- Order entry
- Document management (e.g., requisitions)
- Labeling
- Sorting
- Centrifugation
- Labeling of aliquot tubes
- Decapping
- Pouring of aliquots
- More sorting
- Delivery to laboratory sections
- More sorting
- Preparing work lists
- Labeling analyzer-specific tubes for specimens
- Pouring or pipetting analyzer-specific specimens
- Loading tubes on analyzers
- Performing tests (steps such as extraction, centrifugation, precipitation, and dilution are not specifically listed)
- Unloading analyzers
- Recapping
- Data manipulations (calculations)
- Results review and verification
- Reporting of results
- Delivery of specimens to archival storage system
- Archival storage of specimens
- Reflexive testing
- Repeat testing, diluting, if necessary
- Additional physician-ordered testing
- Specimen retrieval for additional or repeat testing
- Disposal of expired specimens

POINTS TO REMEMBER

When considering new automation or expansion of existing automation:

- Understand the laboratory's needs (moving from the current state to the desired state).
- Review the laboratory's specimen volumes by hour and by day (determine peaks and troughs).
- Review the percentages that are centrifuged, aliquoted, refrigerated or frozen, and shared among lab sections.
- Consider logistics, handling, facilities, and space issues.
- Map the laboratory's workflow. (What are the paths for all specimens?)
- Time the workflow to find bottlenecks and time wasters.
- Rank the laboratory's needs in order of importance and differentiate needs that are "must haves" from needs that are "desired."
- Identify possible solutions that will meet the identified needs.
- Evaluate alternatives that will meet those needs.
- Use performance measures for productivity, turn-around time, and quality to establish baselines against which postautomation performance can be measured.
- Cost justification will likely be required by management, but the performance measures, if credibly predicted, will likely provide the basis for justification.

Problems of Integration

Building a highly integrated laboratory generates many potential problems. Most vendors of clinical laboratory automation systems prefer customer settings in which the integrated analyzers are their own brand. However, many laboratories may prefer to use analyzers from multiple vendors, including the automation system vendor, making integration of instruments and robotic devices from different manufacturers necessary. Decisions must be made concerning which device will be the master controller and which vendor will develop the software that provides overall control of the automation scheme. In addition, individuals or firms that will be responsible for configuration of the automation to the geometry and production schedule of the laboratory must be recruited and trained. Over the past decade, automation vendors have gained considerable experience implementing integrated systems. In addition to expertise provided by the automation vendor, readers should find the CLSI automation standards helpful when integrating devices in their automation model.

Device Integration

One objective in developing an integrated laboratory is to link laboratory instruments and devices into an automated system to maximize the number of automated functions. Automatic specimen introduction requires the development of mechanical interfaces between each laboratory analyzer and devices such as conveyor belts, mobile robots, or robot arms. Some systems have added enhancements, such as electronic interfaces for laboratory instruments, to allow remote computer control of front-panel functions, notification of instrument status information, and coordination of the distribution of specimens between instruments. In the ideal integrated clinical laboratory automation system, the process controller would integrate, automate, and monitor many of the decision-making tasks that occur in the daily activity of a laboratory. For example, the process controller would notify an operator that a particular analyzer (even if it is from a different vendor) may be running low on a reagent or may have a fault condition. The process controller would control and schedule nonanalytic modules such as centrifuges, aliquotters, decappers, and so forth. Most existing LISs have no process control capability, and their interfaces with laboratory analyzers provide only the ability to download accession numbers and the tests requested on each specimen and to upload results generated by the analyzer. The distribution of tasks must be carefully specified in developing such a communications network.

AUTOMATION OF THE ANALYTICAL PROCESSES

The following sections describe basic concepts inherent to automating the analytical process, with a focus on how these concepts have been integrated into clinical chemistry and immunochemistry instrumentation and automated solutions. Advances in analytical automation in clinical chemistry, immunochemistry and immunology, urinalysis, hematology,

coagulation, transfusion medicine, microbiology, mass spectrometry (MS), and molecular diagnostics are then discussed separately.

Basic Concepts

The individual steps required to complete an analysis are referred to as *unit operations* (Box 16.6). Many of these operations (e.g., specimen identification, delivery, and processing) are shared with capabilities of nonanalytical automation discussed earlier in this chapter, although they may also be integrated into the analytical instrumentation itself.

Automated analyzers are generally designed to perform mechanized versions of previously manual laboratory techniques and procedures. Analytical automation provides opportunities for efficiency, reproducibility, and throughput that may not be possible with manual processes. As such, modern instrumentation is engineered in a wide variety of configurations that are influenced by the manufacturer's hardware design, the testing to be performed, the environment in which the instrumentation is to be used, and the instrument and LIS connectivity that are ultimately required.

The most common automated instrument configuration is the random-access analyzer. In **random-access analysis**, testing is performed sequentially (or prioritized, i.e., STAT) on a set of specimens, with each specimen analyzed for a different selection of tests based on its respective clinical orders. Tests in random-access analysis are performed through the use of different vials, packs, or kits of reagents stored onboard the analyzer. This approach permits measurement of both a variable number and variety of analytes in each specimen loaded onto the instrument.

Other analyzer configurations include continuous-flow and centrifugal analyzers. *Continuous-flow analyzers* (e.g., the Technicon AutoAnalyzer) were the first automated analyzers used in clinical laboratories. Initially, these analyzers were used in a **single-channel analysis** configuration and carried out a **sequential analysis** of each specimen. Subsequently, **multiple-channel analysis** versions were developed, in which analysis of each specimen was performed on every channel in parallel. Results of nonrequested tests in the test profile were discarded as unnecessary after the analysis was complete. Inflexibility in the menu of tests that could be performed on these analyzers eventually led

to their replacement in the marketplace by more versatile discrete processing configurations.

Centrifugal analyzers used discrete pipetting to load aliquots of specimens and reagents sequentially into discrete chambers in a rotor. The specimens were subsequently analyzed in parallel (*parallel analysis*) by spinning the rotor to exert centrifugal force to mix the specimens and reagent and to drive the mixtures into cuvettes located on the periphery of the rotor. Such analyzers could be operated in a multiple-specimen/single-chemistry or a single-specimen/multiple-chemistry mode. Centrifugal analysis was not sufficiently versatile to compete with other random-access analyzers and has largely been abandoned for use in high-volume routine laboratory testing. Centrifugal microfluidics, however, is an important component in near-patient testing in which whole-blood specimen processing on small instrumentation enables plasma separation and multiple analyses in separate micro wells.

Specimen Loading

The loading zone of an analyzer is the area where specimens are held in the instrument before they are analyzed. This holding area is often a circular tray, a rack or series of racks built into a cassette, or an array of individual containers ("pucks") into which tubes are inserted. Although most automated instrumentation is now able to identify tubes through techniques such as bar code scanning, some instruments may still require loading of specimens in a defined sequence as specified by a loading list. In most large-scale automated analyzers, specimens may be added continuously by the operator as they become available. This configuration is also most compatible with modular automation and TLA solutions, in which specimens are automatically distributed to component instruments.

A desirable feature of any automated analyzer is the ability to insert new specimens ahead of specimens already in place in the loading zone. This feature allows the timely analysis of a specimen with a high medical priority (i.e., STAT specimens). When specimen identification is machine read, it is usually possible for the operator to reposition specimens in the loading zone. When specimen identification is tied to a loading list, however, insertion or repositioning of specimens must be accompanied by revision of the loading list. The ability to perform add-on testing when a specimen is present on the instrument is another characteristic that can improve efficiency and decrease manual interventions.

In clinical chemistry testing, the specimen for automatic analysis is often serum or plasma. Most automated chemistry analyzers are able to directly aspirate specimen from primary collection tubes of common container sizes. Instrument manufacturers typically specify acceptable specimen container types to ensure physical compatibility of the tube and to prevent inadvertent damage to the instrument. Although the outer tube diameter is most frequently evaluated for instrument compatibility, the inner tube diameter (e.g., double-walled collection tubes) may also impact compatibility with instrument probes or pipettes. The inner tube diameter

may also impact accurate estimations of sample volume in systems with automated volume detection. Many primary collection tubes contain gel separator materials (i.e., separator tubes) that form a barrier after centrifugation between serum or plasma and the cellular elements. Sample aspiration in automated analytical systems must be designed to prevent or withstand probe crashes with the bottom of the tube, as well as crashes or plugging due to gel separators in the specimen container.

Many analyzers also sample from secondary containers (cups or aliquot tubes) filled with sample transferred from an original specimen tube. Often the design of the sampling cup is unique for a particular analyzer. Each cup should be designed to minimize *dead volume*, that is, the excess serum that must be present in a cup to permit aspiration of the full volume required for testing. Many instruments use *short-sample cups* or *false-bottom tubes* to help facilitate testing by automated analyzers with minimal dead volume. When the creation and placement of aliquots or pour-offs into secondary containers is not automated, careful attention must be used in preventing specimen mix-ups, particularly when the secondary container is too small to be directly labeled with appropriate patient identifiers. Secondary containers should be disposable to minimize cost and the potential for cross-contamination, and their shape should, even without a cap, limit evaporation by minimizing the surface area of sample exposed to air.

Specimens may undergo other forms of degradation in addition to evaporation. For example, specimens that contain thermolabile constituents may undergo degradation if held at ambient temperatures. Thermolability is minimized when both specimens and calibrators are held in a refrigerated loading zone. Other constituents such as bilirubin are photolabile. Photodegradation is reduced by the use of semiopaque cups and placement of smoke- or orange-colored plastic covers over the specimen cups. The potential effects of both thermolability and photolability, however, can be minimized by automated instrumentation that tests specimens promptly and efficiently.

Specimen Sampling

The instrument sampling mechanism aspirates specimen from a loaded container for subsequent testing. Automated analyzers may sample fixed or variable volumes depending on the instrument and assay configuration. Sampling takes place using fixed reusable probes or disposable pipettes. Fixed probes limit disposable costs, reduce the need for supply management, and eliminate ongoing operator loading of disposable pipettes. Onboard wash stations for fixed probes are required, however, to reduce the risk of sample or reagent carryover.

Many automated analyzers incorporate *liquid-level sensing* to detect potential short samples, ensure appropriate specimen aspiration, and minimize the risk of probe crashes. Liquid-level detection is often conducted using either pressure or capacitive (radiofrequency) methods. Disposable capacitive pipette tips are available for processes that are vulnerable to carryover. Automated analyzers may

also integrate methods for *clot detection* because clots may result in inadequate specimen volumes being aspirated, as well as plugging of the probe, tubing, or fluidic channels. Instrument “clot errors” that occur in specimens without evidence of detectable clots should raise the suspicion for potential hyperviscosity.

Closed-container sampling systems have also been developed for use in automated chemistry and hematology analyzers. In these systems, the specimen probe passes through a hollow needle that initially penetrates the primary container's rubber stopper. This configuration prevents damage or plugging of the specimen probe while allowing the level sensor to remain active. After the specimen probe is withdrawn, the outer hollow needle is also withdrawn, so the stopper reseals, and no specimen escapes. Closed-container sampling is used widely in hematology analyzers because specimen mixing through gentle tube inversion is commonly required before analysis. Such mixing may even be incorporated into instrument functionality. Closed-container sampling also reduces the risk of contamination or splatter associated with removing the specimen container stopper.

Transmission of infectious diseases by automated equipment is a concern in clinical laboratories. The potential method of transmission by automated equipment is primarily through splatter of serum or blood during the acquisition of samples from rapidly moving specimen probes. The use of level sensors, which restrict the penetration of sample probes into specimens, and provision of software for smoother motion control greatly reduce the possibility of splatter. Additional engineering controls include closed-tube sampling, covers over the specimen probe sampling areas, automated discard to waste bins for disposable sample probes, specimen cups, reaction cuvettes, direct-line plumbing of instrument liquid waste, and appropriate decontamination protocols before routine maintenance or service.

Specimen Introduction and Internal Transport

The method used to introduce a sample into the analyzer and its subsequent transport within the analyzer is the major difference between *continuous-flow* and *discrete processing* systems. In continuous-flow systems, the sample is aspirated through the sample probe into a stream of flowing liquid, whereby it is transported to analytical stations in the instrument. In discrete systems, the sample is aspirated into the sample probe and is then delivered, often with reagent, through the same orifice into reaction cups or other containers where the chemical reaction and analysis take place.

Continuous-Flow Systems

Peristaltic pumps and plastic tubing are used to advance the sample and reagents in **continuous-flow analysis**. Peristaltic pumps trap a “slug” of fluid between two rollers that occludes the tubing. As the rollers travel over the tubing, the trapped fluid is pushed forward and, as the leading roller lifts from the tubing, is added to the fluid beyond it. Peristaltic pumps are still used in some hematology analyzers, instruments with ion-selective electrodes, and wash systems.

Discrete Processing Systems

Air- or positive-liquid displacement pipettes are used for sampling in most discrete automated systems in which specimens, calibrators, and controls are delivered by a single pipette. A pipette may be designed for one of two operational modes: (1) to dispense only aspirated sample into the reaction receptacle or (2) to flush out sample together with diluent. Both systems use a plastic or glass syringe with a plunger, the tip of which is usually made of Teflon. Instrument pipettes may be designed as (1) fixed, (2) variable, or (3) selectable volume. Selectable-volume pipettes allow the selection of a limited number of predetermined volumes. Although pipettes with unlimited or selectable volumes are typically used in systems that allow many different applications, fixed-volume pipettes are used for samples and reagents in instruments dedicated to the performance of only a small variety of tests.

Carryover

Carryover is defined as the transfer of a quantity of analyte or reagent from one specimen or reaction into a subsequent one. Because it erroneously affects analytical results from the subsequent reaction, carryover should be minimized or eliminated. In discrete systems with disposable reaction vessels and measuring cuvettes, carryover is generally caused by the pipetting system. In instruments with reusable cuvettes or flow cells, carryover may also arise from incomplete cleaning of the cuvettes or flow cells between assays.

Most manufacturers of discrete systems reduce sample-to-sample carryover by using disposable pipette tips or by incorporating wash stations for the sample probe that flush the internal and external surfaces of the probe with copious amounts of wash solution. An adequate ratio of flush and rinse to specimen volume controls carryover in many cases to acceptable limits. Appropriate choice of sample probe material, geometry, and surface conditions also influences carryover. Some systems clean the outside of the sample probe to prevent transfer of a portion of the previous specimen into the next specimen cup. Use of disposable sample probe tips eliminates the risk of contamination of one sample by another inside the probe, as well as the risk of carryover of one specimen into a specimen in the next cup, because a new pipette tip is used for each pipetting.

Although many high-volume automated chemistry analyzers have fixed reusable probes, instrumentation associated with processes that are more vulnerable to carryover and contamination (e.g., serology and molecular diagnostics) generally incorporate disposable pipettes for sample aspiration. For example, the reduction of sample-to-sample carryover is a more stringent requirement for automated analyzers that perform immunoassays in which some analytes (e.g., human chorionic gonadotropin) have a wide range of concentrations. Some systems use extra steps, such as additional washes, or an additional washing device to reduce carryover for selected tests to acceptable limits. Because extra steps reduce overall throughput, additional rinsing functions are initiated (by computer operator selection) only for assays with large analytical measurement ranges (AMRs).

Sample-to-sample carryover can be detected by the preparation of two sample pools—one having a very high analyte concentration (H), the other having a low concentration (L). By running sequences of tests (e.g., HHHLLLHHLLHLL) if sample-to-sample carryover is present, higher results will be noted in the low-concentration sample analyses that immediately follow a high-concentration sample.

Reagent-to-reagent carryover can also occur on discrete systems that use a common probe for pipetting reagents. Its minimization or elimination requires use of the same approaches described for sample-to-sample carryover. Detection of reagent-to-reagent carryover can be difficult for end users and usually requires involvement of the instrument vendor.

Sample Pretreatment

Analytical procedures sometimes require the capability to remove proteins or other interferents from specimens to ensure the specificity of an analytical method. Dialysis, column chromatography, extraction, and filtration have been used for this purpose. Additional pretreatment processes include specimen concentration and/or dilution to bring an analyte of interest into an assay's AMR. Automation of pretreatment processes through offline or integrated specimen processing systems can improve the efficiency of these procedures. Sample pretreatment steps may also be integrated into assays designed for automated platforms. Examples include the addition of reagents that displace analytes from their endogenous binding proteins and instrument addition of red blood cell (RBC) lysing reagents in automated glycosylated hemoglobin or HbA1c measurements.

Reagents

Reagent Management and Configuration

Reagent management is an important consideration in choosing automated instrumentation. Analytical systems may require that different reagents be stored at ambient, refrigerated (4°C), or frozen (−20°C or −80°C) temperatures. Availability of adequate reagent storage close to instrumentation is an important consideration in implementing efficient analytical systems. Reagents, calibrators, and quality control (QC) materials that are supplied as lyophilized (dry) powder requiring reconstitution can require significant ongoing manual processing on the part of instrument operators. Some analytical systems have the capacity for onboard reconstitution of certain reagents, QC, or calibrators.

Many automated systems use liquid reagents stored in plastic or glass containers. For analyzers with a working inventory maintained in the system, the volumes of reagents stored onboard are often optimized based on the desired number of tests to be performed without operator intervention. Such analyzers often track the amount of reagent that is currently onboard and notify the operators when a replacement is required. In larger systems, reagent storage compartments may be maintained at refrigerated temperatures to increase onboard stability. Some analyzers have the ability to cap reagents while not in use to decrease evaporation and reagent

degradation. Larger automated analyzers may have the ability to load new reagent packs (and discard empty packs) without interrupting the testing process or placing the instrument in a “standby” mode. Additionally, many automated instruments allow the loading of more than one similar type of reagent pack so that testing is not delayed when the first pack runs empty. Having an excess number of available reagent positions on automated instrumentation allows for optimization of reagent management to match the laboratory's daily workflow with minimal operator involvement. For analyzers in which specimens are not processed continuously, in-use reagents are often stored in laboratory refrigerators and are only introduced onto instruments when required for testing.

Reagent Identification

Labels on reagent containers include information such as (1) reagent identification, (2) volume of the contents or the number of tests for which the contents of the containers are to be used, (3) expiration date, and (4) lot number. Many reagent containers carry bar codes or RFID tags that contain some or all of this information. Advantages of using reagent bar codes include (1) facilitation of inventory management, (2) the ability to insert reagent containers in random sequence, and (3) the ability of the system to track in-use reagent lot numbers and document that appropriate calibration and QC procedures were performed on a specific lot or pack before testing. Furthermore, when a bar code reader is coupled with a level-sensing system on the reagent probe, it alerts the operator as to whether a sufficient quantity of reagent exists to complete a workload. Bar codes on reagent containers may also contain information about calibrators, such as the definition of a calibration curve algorithm and values of curve constants defined at the time of reagent manufacture. Accompanying calibrator materials provided in their own bar code tubes at the time of manufacture ensure that calibration functions are integrated properly into the analysis. Inventory management systems (tied to bar codes or RFID tags) can be used to track reagent usage and reorder reagent to prevent depletion of inventory and corresponding test delays. Such systems (combined with vendor reagent lot sequestering programs) can decrease the need for new-lot workups and therefore maximize instrument and operator productivity.

Vendor-Supplied Versus User-Defined Reagents

Automated analyzers can be classified as “open” or “closed” with respect to reagent compatibility. A “closed” system analyzer is one in which reagents or calibrators (or both) are provided only by the instrument manufacturer and other reagents or methods cannot be used. Closed systems can be restricted based on proprietary licensing or technical restrictions of reagent components, reagent pack size and shape, or software restrictions associated with compatibility of vendor bar codes or the ability to configure custom test parameters. In an “open” analyzer, the operator can change the parameters related to an analysis and load user-defined reagents (UDRs) by preparing “in-house” reagents or using reagents from alternative suppliers. Such analyzers usually have considerable flexibility and

adapt readily to new methods and analytes. Many vendors of automated analyzers allow a limited number of UDRs on an otherwise closed system, with restrictions based on technical (instrument-related) or contractual limitations. Advantages of UDRs include decreased cost, increased flexibility, and the ability to optimize assay performance. Disadvantages of UDRs may include additional regulatory requirements for laboratory-developed tests, manual processes associated with reagent preparation, lack of manufacturer-associated bar code information on reagent packs, and smaller peer group sizes in proficiency testing challenges.

Reagent Delivery and Mixing

Liquid reagents are often acquired and delivered to mixing and reaction chambers by pumps (through tubes) or by positive-displacement syringe devices. In analyzers in which more than one reagent is acquired and dispensed by the same syringe, washing or flushing of the probe is essential to prevent reagent carryover. Reagent carryover may interfere with subsequent reactions depending on which combinations of tests were sequentially performed on the instrument. Reagent carryover experiments are particularly important when considering UDR kits because UDRs would not have been evaluated by the instrument vendor for potential interference because of constituent carryover.

Chemical Reaction Phase

Sample and reagents react in the chemical reaction phase. Factors that are important in this phase include (1) the vessel where the reaction occurs; (2) the cuvette where the reaction is monitored; (3) the timing of the reaction(s); (4) the mixing and transport of reactants; (5) the thermal conditioning of fluids; and (6) for some immunoassay systems, the separation of bound and unbound fractions.

Type of Reaction Vessels and Cuvettes

In continuous-flow systems, each specimen passes through the same continuous stream and is subjected to the same analytical reactions as every other specimen and at the same rate. In such systems, the reaction occurs in the flow-through component. In discrete systems, each specimen has its own physical and chemical reaction space, separate from every other specimen. Discrete analyzers use either individual (disposable or reusable) reaction vessels transported through the system after sample and reagent have been dispensed, or they use stationary reaction chambers.

Reaction vessels (typically cuvettes) are reused in many instruments. The time before reusable reaction vessels must be replaced depends on their composition and the washing mechanisms used. Some manufacturers have computer algorithms that automatically control when individual reaction vessels should be replaced, depending on how many assays and what types of assays have been performed in a given cuvette.

Mixing of Reactants

Various techniques are used to mix reactants. In discrete systems, these include (1) forceful dispensing, (2) magnetic

stirring, (3) vigorous lateral displacement, and (4) physical stirring. Dry reagent systems obviate the need for mixing because the serum completely interacts with the dry chemicals as it flows through the matrix of the reaction unit. However, regardless of the technique used, mixing can be a difficult process to automate and one that may contribute to reaction-to-reaction carryover among reused components. Inadequate mixing can lead to erroneous test results that may only be detectable by QC failures.

Thermal Regulation

Thermal regulation requires the establishment of a controlled-temperature environment in close contact with the reaction container and efficient heat transfer from the environment to the reaction mixture. Various technologies have been used for temperature regulation, including air baths, water baths, and Peltier devices. Onboard water baths often require specific maintenance and cleaning, particularly if the reaction monitoring system involves passage of light through the water bath to a reaction cuvette. Automated analyzers may also be influenced by external operating temperatures in the laboratory. Most vendors define acceptable temperature (and humidity) limits for their instruments.

Separation in Immunoassay Systems

Automation of immunoassay procedures often requires the separation of free and bound fractions of heterogeneous immunoassays; see [Chapter 15](#) for additional information. Several approaches have been used to accomplish this separation. For example, automated immunoassay analyzers may use bound antibodies or proteins in a solid-phase format. With this approach, the binding of antigens and antibodies occurs on a solid surface to which the antibodies or other reactive proteins have been adsorbed or chemically bonded. Different types of solid phases are used, including (1) beads, (2) coated tubes, (3) microtiter plates, (4) magnetic and non-magnetic microparticles, and (5) fiber matrices.

Measurement Approaches

Automated chemistry analyzers have traditionally relied on photometers and spectrophotometers to measure the absorbance of the reaction produced in the chemical reaction phase; see [Chapter 9](#) for additional information. Alternative approaches now incorporated into analyzers include reflectance photometers, fluorometers, and luminometers. Immunoassay reactions that produce fluorescence, chemiluminescence, and electrochemiluminescence enhance sensitivity. Ion-selective electrodes and other electrochemical techniques also are quite common. Many of these methods are discussed in detail elsewhere in this textbook (see [Chapters 9 and 15](#)).

Postassay Processing

After a test is performed on a specimen, additional automated or manual specimen processing may still be required to obtain a final, clinically reportable result. Two such processes that are commonly performed are dilutions and repeat testing before reporting.

Dilutions

If initial results are above the assay's AMR, dilutions may be required to bring the analyte concentration into the linear range. Dilutions may also be used to exclude the possibility of antigen excess ("hook effect"; see [Chapter 15](#)). Some instruments can perform automated dilutions by (1) pipetting less specimen volume into the reaction mixture, (2) pipetting more reagent into the reaction mixture, or (3) using onboard dilution vessels. Instrument dilutions may be performed automatically (based on analyzer settings) or triggered by operator request. Analyzers that are unable to perform autodilutions may still notify operators when an offline dilution is required. Many analyzers will then allow the operator to input the dilution factors so that final results are calculated automatically to limit the chance of error.

Repeat Testing

Many laboratories have protocols that require certain assays to be automatically repeated before reporting. Some examples include critical results or tests for life-altering diagnoses. Improved analytical methods and instrumentation have challenged the need for routine repeat testing. Regardless, many automated analyzers allow configurations for repeat testing without operator intervention, thus decreasing the time for result availability and communication to the ordering provider.

Signal Processing, Data Handling, and Process Control

The interfacing and integration of computers into automated analyzers and analytical systems has had a major impact on the acquisition and processing of analytical data. Analog signals from detectors are converted to digital signals. Computer software then processes the digital data into useful and meaningful output. Data processing has allowed automation of complex calibration relationships. Computer workstations provide a central point of communication with the user regarding (1) instrument status, (2) order entry, (3) result display, (4) QC functionality, (5) instrument troubleshooting, (6) instrument maintenance, and (7) result release to the LIS. For small laboratories, these processes may be tracked primarily within an individual instrument computer and the LIS. For laboratories that have multiple analyzers (often from different vendors), tracking of these processes within additional computer systems between the instruments and LIS (termed *middleware*) can enhance overall efficiency.

Test Autoverification

Autoverification is the process whereby patient results generated from interfaced instruments are compared by computer software against laboratory-defined acceptance parameters. If results fall within these defined parameters, the results are automatically released for reporting with no additional laboratory staff intervention. Any data that fall outside the defined parameters are reviewed by laboratory staff before reporting. Autoverification has been implemented in a variety of ways, such as by using LIS to compare results against acceptance

Fig. 16.5 Example of an integrated chemistry and immunoassay system. The ARCHITECT ci8200 (Abbott Diagnostics) combines a c8000 clinical chemistry module (*left*) with an i2000SR immunoassay module (*right*) in one connected platform. (Courtesy Abbott Diagnostics, Lake Forest, IL.)

parameters, or alternatively, by performing this function in middleware. Most autoverification systems use rule-based decision logic. The rules applied in such systems require careful development and validation by laboratories before and after they are implemented. Regulations regarding autoverification are incorporated into most laboratory accreditation programs.

Instrument Clusters

To reduce labor costs, instrument manufacturers have developed approaches that allow a single technologist to simultaneously control and monitor the functions of several instruments or modules. Initially, such workstations were configured with clusters of identical instruments, such as chemistry, immunochemistry, or hematology analyzers. Advanced instrument clusters may incorporate different chemistry, immunochemistry, or hematology analyzers into the same cluster or combine different types of detection systems into a platform (see [Figs. 16.3, 16.5, and 16.6](#)).

A cluster of analyzers has its own central computer control module with software designed to assist the operator in monitoring the functions of each analyzer and to aid in the review of laboratory results generated by the cluster. Access to the many front-panel functions of each analyzer is provided by the interface between the analyzer and the central control module. Thus, the operator loads specimens onto each instrument (or a shared input module) and then monitors subsequent instrument operation and result review from a central workstation. Incorporating the activities of multiple instruments into a single integrated workstation can improve overall efficiency.

Microtiter Plate Systems

Microtiter plate systems are commonly used in immunoassays and nucleic acid analyses. Microtiter plates (as used for enzyme-linked immunosorbent assays [ELISAs]) are usually made of polystyrene and have 48 or 96 wells that are coated with an antibody that is specific for the antigen of interest. After incubation of serum in the microtiter plate well, the well is washed to remove unbound antigen, and a second antibody

Fig. 16.6 Example of an integrated chemistry and immunoassay system. The Cobas 8000 (Roche Diagnostics) modular analyzer series configuration shows (from left to right) a core unit, an ion-selective electrode module, as well as c702 and c502 chemistry and e602 immunoassay instruments. Module sample buffers allow additional capacity and random access distribution of racks. (Courtesy Roche Diagnostics, Switzerland.)

with conjugated indicator enzyme is added. After a second incubation period, the well is washed to remove the unbound conjugate. A color-producing product is developed by the addition of enzyme substrate, and the reaction is terminated at a specific time. With the development of automated pipetting stations (see next section), the liquid handling steps have been fully automated to make microtiter plate assays a viable technology for carrying out large numbers of immunoassays. Measurement of absorbance and data processing are also automated in many instruments.

Automated Pipetting Stations

Automated pipetting stations have a Cartesian (also referred to as linear) robot with a pipette fixed to the end of a probe that moves within a rectangular space. The probe is capable of moving in the x-, y-, and z-axes. Liquids may be aspirated and dispensed in any location within the rectangular space. Pipetting stations may be used to automate an analytical procedure for which an automated analyzer does not exist or cannot be cost justified. Pipetting robots should (1) be relatively easy to program, (2) rarely malfunction, and (3) be capable of delivering aliquots of liquids with extreme precision and accuracy. Multiple-channel pipetting robots allow parallel processing of specimens with 8- or 12-channel probes to handle microtiter plates.

AREAS OF ANALYTICAL AUTOMATION

Although the automation principles discussed earlier focus primarily on clinical chemistry applications, the following sections describe aspects of analytical automation that are unique to individual disciplines, including (1) clinical chemistry, (2) immunology and immunochemistry, (3) urinalysis, (4) hematology, (5) coagulation, (6) transfusion, (7) microbiology, (8) mass spectrometry, and (9) molecular diagnostics.

Clinical Chemistry

Automated systems in clinical chemistry can be differentiated based on (1) the volume of testing that is performed on the

Fig. 16.7 Example of an automated bench-top special protein analyzer (Optilite, The Binding Site Group). (Courtesy The Binding Site Group Ltd., Birmingham, United Kingdom.)

instruments(s) and (2) their ability to connect to instrument clusters or a larger laboratory automation system.

Laboratories that perform a lower volume of testing or that have limited available floor space may choose smaller analyzers to minimize cost, complexity of maintenance, and instrument footprint. Many low-volume laboratory automated chemistry instruments include similar functionalities to those seen on high-volume instruments, including a diverse assay menu, multiple methods of analytical detection, compatibility with UDRs, onboard QC management, and LIS connectivity. Smaller instruments may also be used in large-volume laboratories for specialized methods, where test order volume or assay compatibility is not supported or not cost-effective on higher volume instruments (Fig. 16.7). For example, use of smaller instruments for esoteric testing may be amenable to **batch analysis** with less reagent waste.

Automated instruments for large-volume laboratories typically improve efficiency by handling more tests per hour

Fig. 16.8 Example of a high-throughput automated clinical chemistry system. with a larger capacity for specimens and reagents (Fig. 16.8). Larger instruments may have more physical plant (infrastructure) requirements than their smaller counterparts, including floor space, ventilation, water supply, electrical, and drainage. Although these requirements may place greater initial costs on a larger automated system, when they are in place, they support greater efficiency of instrument operation. Larger automated instruments also typically offer greater options for connectivity in instrument clusters and TLA solutions.

Larger systems may also have more complex maintenance procedures. Furthermore, instrument downtime for service may have a significant impact on clinical operations with high-volume consolidated platforms. For this reason, many high-volume laboratories are designed to incorporate instrument and assay redundancy so that if one analyzer is down for service, clinical testing can still be conducted on separate instruments. This is particularly important for laboratories that support acute-care, inpatient, and emergency department operations.

Along with routine chemistry analyzers that perform traditional photometric and potentiometric measurements, automation in clinical chemistry also includes specialized instrumentation for specific clinical needs. Blood gas analysis (including instrumentation in clinical laboratories, STAT laboratories, and point of care or POC) is conducted on automated instrumentation. These platforms may include built-in QC assessment; single- or multiple-use reagent systems; and quantification of additional analytes that may be useful to near-patient testing, including electrolytes, glucose, ionized calcium, lactate, pH, hemoglobin, or hematocrit. Automated platforms also exist for other specialized techniques such as HbA1c measurement, protein electrophoresis, osmometry, viscosity, and erythrocyte sedimentation rate.

Immunochemistry and Immunology

Antibody-based detection methods are incorporated into many automated instruments and include nephelometry, turbidimetry, and a wide range of immunoassays incorporating enzymes, labels, fluorophores, and chemiluminescent detection methods (see Chapters 9 and 15). One advantage of using antibodies in automated instrumentation is that by

Fig. 16.9 Example of an automated immunofluorescence microscopy system (EUROPattern, EUROIMMUN). (Courtesy EUROIMMUN.)

varying reagents (antibodies), the same instrumentation may be used for the detection and quantification of many different analytes.

Along with discrete processing systems, automated immunoassay platforms may also be designed for microplates and microwells, including ELISAs and cell-based immunofluorescence assays. Automated indirect immunofluorescence microscopy systems are also available (Fig. 16.9). Automated systems are offered for processing of Western blots and immunoblots, techniques that have otherwise been very manually intensive. Finally, bead-based multiplex systems allow for the detection of multiple analytes in the same reaction mixture. Such systems can decrease the specimen volume required for parallel analyses.

Urinalysis

Although many of the same analytical principles are used for the quantification of serum and urine chemical constituents, traditionally it has been more challenging to fully automate testing of urine because of the broad range of urine analyte concentrations. This requires a low limit of detection to measure low concentrations and expanded linearity to permit

Fig. 16.10 Example of an automated urinalysis system. The Iris iRICELL3000 (Beckman Coulter) combines urine chemistry analysis (iChemVELOCITY, *right*) with a digital flow morphology module (iQ200SPRINT, *left*). (iRICELL Copyright 2016 Beckman Coulter, Inc. All rights reserved. Used with permission.)

measurements of high concentrations without dilution. This requirement, together with the relatively low demand for urine tests compared with that for serum, slowed the development of analyzers designed specifically for urine constituents. Several automated urinalysis instruments are now commercially available for chemical analyses (automated and semi-automated test strip reading by reflectometry) and analysis of sediment, particles, or cellular elements using flow cytometric or microscopic analysis. Many systems combine both chemical and particle analysis modules into a workcell (Fig. 16.10) so that particle analysis can be conducted automatically on specimens with abnormal test strip results. Instruments for microscopic urine analysis have also been applied to automating body fluid cell counting. Finally, although manual reading of urine test strips is still commonly performed as a POC test, small semiautomated instruments are available for Clinical Laboratory Improvement Amendments (CLIA)-waived automated reagent strip interpretation.

Hematology

Analyzers that perform a complete blood count have been automated through the use of (1) the “Coulter principle,” which is based on cell conductivity; (2) light scatter; (3) flow cytometry; and more recently, (4) digital microscopic analysis. Individual blood cells are analyzed by application of one or more of these techniques. The Coulter principle is based on changes in electrical impedance produced by nonconductive particles suspended in an electrolyte solution as they pass through a small aperture between electrodes. RBCs, white blood cells (WBCs), and platelets are identified by their sizes.

Flow cytometry typically counts cells (often stained with supravital or fluorescent dyes) that travel in suspension, one by one, past a laser light source. Scattered light and emitted light are collected in front of the light source and at right angles, respectively. Information derived through measurement of light scatter when a cell is struck by the laser beam is then used to estimate (1) cell shape, (2) cell size, (3) cellular granularity, (4) nuclear lobularity, and (5) cell surface structure. Although some cell counters classify WBCs using the Coulter principle, cell conductivity, and light scattering

of unstained cells to differentiate cell types, other cell counters use multiple flow cytometry channels or a combination of approaches.

When abnormal cells or cell counts outside of predetermined limits are observed in automated counting methods, it may be necessary to generate a blood smear for additional microscopic review or generation of a manual differential. Integrated hematology systems may include automated slide makers and slide stainers to limit the manual intervention involved in creating and labeling slides (Fig. 16.11). In addition, advances in slide imaging have enabled the development of automated systems to classify and count cell types based on a digital scan of the slide or a representative number of regions of interest. Automated digital imaging systems may also offer electronic review of categorizations by an operator, as well as electronic storage and sharing of images with clinicians outside the laboratory.

Coagulation

Most coagulation testing is now performed on automated analyzers. A variety of methodologies are used, including optical and mechanical clot detection, as well as turbidimetric, chromogenic, and antibody-based analyses. Many instruments permit use of UDRs for more specialized coagulation testing. Connectivity to TLA systems is an option with some instrumentation, and this allows for automated specimen handling and centrifugation before coagulation testing. Additional instrumentation and methods used in coagulation testing include aggregometers, platelet function analyzers, and thromboelastography. Automated POC and near-patient devices are also available for many coagulation tests including prothrombin time, international normalized ratio, partial thromboplastin time, and activated clotting time.

Transfusion Medicine

Advances in laboratory automation have also impacted most areas of blood banking and transfusion medicine. Robust information technology systems to track donor history, blood component traceability, bar coding, transfusion-transmissible diseases, immunohematological testing, inventory

Fig. 16.11 Example of an automated hematology system. A scalable Sysmex XN-9000 Automated Hematology System, including three XN-10 hematology test modules and one SP-10 module for slide making and staining (left). (Courtesy Sysmex America, Inc., Lincolnshire, IL.)

Fig. 16.12 Example of an automated transfusion medicine analyzer. The ORTHO VISION Analyzer (Ortho Clinical Diagnostics) offers automated immunohematology testing. (Courtesy Ortho Clinical Diagnostics, Raritan, NJ.)

management, and component administration all work to improve the safety and traceability of transfused blood products. Automation at blood collection sites through apheresis donations helps to maximize the yield of specific blood component donations. Automated component processing systems at blood centers improve the efficiency of postdonation handling of blood products, thus enabling fresh components of blood products (with less chance of processing errors) to ultimately be distributed for transfusion.

Traditionally, immunohematological testing in the blood bank was conducted primarily through test tube RBC agglutination techniques. Both small- and large-scale systems are now available to automate many of these techniques, including RBC typing (ABO, Rh), antigen typing, screening and identification of alloantibodies, direct antiglobulin testing (DAT), dilutions, titrations, reflex testing, and crossmatching of potential products for transfusion (Fig. 16.12). In general, automated blood bank systems are as reliable and sensitive as routine manual testing. Advantages include less opportunity for processing and transcription errors. The decision to automate immunohematology testing includes a variety of factors, such as staffing and expertise, test volumes, variation

in orders between day and night shifts, workflow considerations, and overall expense. Finally, RBC molecular typing (genotyping) may further refine how donor and recipient screening is automated within the blood bank.

Microbiology

Clinical microbiology has recently undergone a transition toward far greater automation. Although standalone instrumentation for aseptic plate preparation, blood culture incubation and microbial detection, biochemical identification, and antimicrobial susceptibility have all been commercially available for years, much of the processing and interpretation steps within the microbiology workflow remained largely manual. Both standalone and TLA solutions are now available, however, to automate many of these processes.

TLA microbiology solutions with tracking systems have been designed to handle preanalytical, analytical, and postanalytical steps (Fig. 16.13) and may include specimen decapping and recapping; Petri dish bar code labeling; plate inoculation and streaking; Gram stain preparation; automated incubation (O_2 and CO_2); high-resolution digital imaging of plates; and colony sampling for biochemical identification, antibiotic susceptibility testing, and seeding of plates for subsequent matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometric analysis. MALDI-TOF is a rapidly growing area of microbiology and is used for organism identification.

POINTS TO REMEMBER

Analytical Automation

- Analytical automation has impacted all areas of laboratory medicine.
- Along with automating the testing phase, analyzers may incorporate specimen handling, reagent management, QC, and result review.
- Automated processes, including liquid-level sensing, clot detection, closed-container sampling, and instrument auto-dilution, help to improve the efficiency of laboratory testing.
- Analytical systems can be organized into clusters or TLA solutions, allowing operators to control multiple instruments.

Molecular Diagnostics

Automation has been crucial for the expansion of molecular diagnostics into the clinical laboratory. Once a guaranteed money sink that only academic laboratories could afford, the realm of DNA and RNA analysis is now a cherished part of most laboratories, large or small. **Molecular diagnostics** has come to mean analysis of DNA or RNA, unfairly excluding proteins, electrolytes, small molecules, and other polymers.

Molecular diagnostics is a relatively new field, with the structure of DNA only described in 1953. The first molecular method with the necessary sensitivity and specificity to detect sequence changes in DNA was **Southern blotting**, introduced by Edwin Southern in 1975. Southern blotting was the antithesis of automation requiring multiple manual steps, including DNA isolation, treatment with restriction enzymes, electrophoresis, blotting, preparation of radioactive probes, hybridization of the probes, and finally development of signal by exposure to film. Early sequencing was also very labor intensive, requiring cloning of the fragment to be sequenced and multiple steps to eventually read the sequence base by base from different sized fragments separated by electrophoresis. Although many of the steps in Southern blotting and sequencing can be automated, it was the simplicity of the **polymerase chain reaction (PCR)** in the 1980s and **real-time PCR** in the 1990s that popularized molecular diagnostics in clinical laboratories.

Automation has had major impacts in (1) nucleic acid preparation, (2) liquid handling, (3) amplification, and (4) analysis of molecular diagnostic assays. Nucleic acid preparation typically involves (1) cell lysis, (2) separation from proteins, and (3) purification from interfering substances. Sample preparation instruments today often rely on reversible binding to silica-coated paramagnetic beads that can easily be washed to remove impurities. Most molecular methods require several mixing or transfer steps that can be automated by liquid handling. For example,

PCR requires mixing reaction components together before thermal cycling. Although many components are common to all reactions and can be combined as a “master mix,” template DNA and primers are unique and must be pipetted individually for each reaction. One common use for the Cartesian pipetting stations mentioned previously is to automate the setup of such reactions when large numbers of samples or assays need to be processed. Instead of onsite automation just before the assay, another alternative is to perform the automation well before the assay is performed. For example, primer plates can be made, dried, and stored by a Cartesian automation station that patterns different primer pairs on a 96-well plate when multiple assays are performed together, greatly reducing the complexity for the performing technologist. Commercial vendors can provide one- or two-dimensional arrays of targets, including millions of hybridization targets on a chip for expression profiling, genotyping, or copy number assessment. The commercial use of automation can provide products to the laboratory that greatly reduce the complexity at the site where the assay is performed, albeit often with a loss in flexibility.

Although single-molecule techniques are now available, most molecular methods require target or signal amplification for visualization. For example, PCR requires repetitive temperature cycling of multiple reactions between two or three temperatures, a task begging for automation that has resulted in many different instruments. Isothermal methods of amplification were developed many years later and nicely match rapid, near-patient testing. Automated analysis of molecular assays can be as simple as size interpolation of samples from a ladder of standards on electrophoretic gels or as complicated as aligning billions of massively parallel sequence reads against a reference human genome. Such massive data analysis is only possible because of a parallel increase in computer storage and computational speed enabled by modern computers.

Sequencing Automation

Traditional Sanger sequencing is a complicated multistep process, originally performed with radioactivity on 2D slab gels. By using fluorescence instead of radioactivity and by acquiring, storing, and analyzing sequence information from a one-dimensional tube gel directly on a computer, the analysis part of sequencing was automated. Although this was a great advance and led to the widely used capillary sequencers of the 1990s and 2000s, only the final task of data acquisition and analysis was automated. The process still required (1) initial amplification by PCR, (2) cleanup of the PCR product, (3) addition of cycle sequencing reagents, (4) cycle sequencing with dideoxy termination, (5) cleanup of the termination products, and (6) transfer to a capillary electrophoresis instrument. Although many of these steps were eventually automated in the largest sequencing centers, completely integrated liquid handling for sequencing was seldom obtained in clinical laboratories. Massively parallel sequencing in the mid-2000s introduced entirely new workflows. Sequencing by synthesis is now most common and uses the stepwise addition of fluorescently labeled reversible terminators. The amplification, synthesis, and data acquisition steps are entirely automated. Even though sample preparation is complex and mostly manual, the effort is justified by the massive amounts of data generated. Data analysis is also complex and not standardized, requiring custom software “pipelines” to align each sequenced read to a reference sequence, determine or call each base, and determine the clinical significance of each variant from the reference sequence.

Polymerase Chain Reaction Automation

PCR was first automated before thermostable polymerases were available. Because the enzyme was inactivated in each cycle at the high temperatures needed for DNA denaturation, enzyme needed to be replenished in each cycle. Automation required not only temperature cycling but also the addition of reagents in each cycle. The combination of thermal control and repetitive reagent addition was complex and expensive. Although the liquid handling could be automated, it was made obsolete by the use of thermostable polymerases that could withstand the required DNA denaturation temperatures. A simple change in the process greatly simplified the automation requirements.

The thermal cycling provided by PCR instruments was at first slow, requiring 4 hours for amplification. Most common platforms used metal blocks that held samples in tubes

or plates that were convenient to handle, although circulating systems allow better thermal control and faster cycling. Rapid-cycle PCR was developed in the early 1990s and reduced PCR amplification times down to 10 to 15 minutes. More recently, extreme PCR amplifies small products in as little as 15 seconds, indicating that the speed of PCR is limited by the instrumentation, not the biochemistry. Often, physical automation cannot keep up with the speed of molecular reactions.

Real-time PCR combines fluorimetry with thermal cycling, allowing fluorescence monitoring of double-stranded DNA production during PCR. When the fluorescent signal is acquired once each PCR cycle, template quantification can be automated. When the fluorescent signal is acquired during temperature transitions, melting curves are generated that monitor DNA hybridization. Both applications of quantification and melting curve analysis are enabled by the simple automation of fluorescence signal acquisition. Nucleic acid quantification, previously very difficult to obtain by PCR, is greatly simplified and used extensively in transcript quantification. Melting analysis and its more precise sibling, high-resolution DNA melting, have replaced manual gels in many applications and provide closed-tube genotyping, scanning, and relative quantification without probes. When both control and acquisition are automated, powerful systems, such as real-time PCR can result, similar to many automated laboratory instruments.

Throughput and Molecular Applications

Throughput is defined as the number of samples processed in a given period of time. Automation can improve throughput either by increasing the batch size of a run (the number of samples analyzed at once) or by decreasing the turn-around time (the time it takes to process each sample or run). Automation has successfully improved throughput by increasing batch size, from single samples, to strips of 8 or 12, to 96-, 384-, or even 1536-well plates. For example, large automated molecular microbiology systems are used for infectious disease testing for HIV, hepatitis C virus, and several other major infections. Less emphasis has focused on decreasing turn-around time, although rapid (<1-hour) sample-to-answer systems for molecular targets are now approved by the Food and Drug Administration. The symbiosis of automation and molecular testing will continue to lead to faster, better, and less expensive solutions for clinical laboratories.

REVIEW QUESTIONS

1. Which type of specimen label has resulted in a reduction in preanalytical specimen identification errors and is used extensively in automated specimen identification?
 - a. Social Security numbers stamped on all individual specimen containers
 - b. Hospital identification numbers written on tubes of blood
 - c. Labels containing bar codes that are unique identifiers
 - d. Medical accounting numbers written on the lids of all containers
2. One serious issue with the use of accelerating/decelerating pneumatic tube systems to deliver specimens to the laboratory is the occurrence of:
 - a. clot formation.
 - b. hemolysis.
 - c. specimen breakage.
 - d. specimen volume loss.

3. Which of the following activities are important in the evaluation of the need for automation and in identifying the solution?
 - a. Workflow mapping
 - b. Plotting the volumes of arriving specimen by the hour of the day
 - c. Vendor analyses and presentations of findings
 - d. Visiting laboratories with installed systems and asking frank questions
 - e. All of the above
4. The transport of a quantity of analyte or reagent from one specimen reaction into a subsequent one is referred to as
 - a. batching.
 - b. carryover.
 - c. misdelivery.
 - d. indiscrete handling.
5. What makes automation of the polymerase chain reaction much easier?
 - a. Capillary electrophoresis
 - b. Fluorescence feedback to automatically control the denaturation temperature
 - c. Primer specificity
 - d. Thermostable polymerase
6. Future opportunities for automating massively parallel sequencing include:
 - a. Sample preparation
 - b. Capillary electrophoresis
 - c. Thermostable polymerase
 - d. Quantitative reverse transcriptase PCR

Point-of-Care Testing

Andrew St. John, Maurice O’Kane, Christopher P. Price

OBJECTIVES

1. Define point-of-care testing (POCT) and other terms used to describe this process.
2. Describe the analytical requirements and technological considerations for POCT.
3. Describe examples of POCT devices.
4. Describe the interrelationship between informatics and POCT.
5. Describe key factors in the implementation and management of POCT programs.
6. Discuss types of evidence that can be used to demonstrate the effectiveness of POCT.

KEY WORDS AND DEFINITIONS

Accreditation The formal recognition by an independent body that the process or service operates according to defined standards.

Analyte The substance that is to be measured (also known as a *measurand*).

Audit The examination of the quality of performance of a process measured against a predetermined standard.

Connectivity The property of a device that enables it to communicate with an information system (e.g., a laboratory information system) for the primary purposes of transmitting patient data from the device to the patient’s record, and for monitoring the performance of the device.

Effectiveness Demonstrating through evidence that POCT brings benefits to patients and the overall clinical care process.

Fluidics Process by which liquid moves within a confined space, as in the case of a narrow tube or a porous matrix. Such processes include surface tension, diffusion, and the use of pumps.

Informatics The structure, creation, management, storage, retrieval, dissemination, and transfer of information.

Operator Interface The part of a device that the operator is required to use in order for the device to work (e.g., switch on a reader, enter a patient or sample identification, or calibrate the device).

Point-of-Care Testing (POCT) A mode of testing in which the analysis is performed close to the patient rather than in a laboratory.

Quality Management The act of overseeing all activities and tasks needed to maintain a desired level of excellence.

Recognition Element A molecule that is used for the recognition (and sometimes capture) of the analyte of interest (e.g., enzyme, antibody, affinity ligand).

Sensor A device that receives and responds to a signal or stimulus. There are many examples in life, including the receptors of the tongue, the ear, and so on.

Transducer A substance or device that converts input energy in one form into output energy of another form.

Point-of-care testing (POCT) can be simply defined as “medical testing at the site of patient care” that therefore allows more rapid clinical decision-making with the possibility of improved health outcomes. Many other terms have been used to describe POCT, including “bedside,” “near patient,” “physician’s office,” “extra-laboratory,” “decentralized,” “off-site,” “satellite,” “kiosk,” “ancillary,” and “alternative site” testing. POCT also includes “self-testing,” where the patients perform the tests themselves. Self-monitoring for blood glucose and prothrombin time or international

normalized ratio (INR) together form the largest segment of the POCT market.

Advances in a range of technologies and manufacturing processes such as thin film sensors, semiconductor engineering, plastic moulding, microfluidics, nanotechnology, and consumer electronics, make it possible to adapt most of the methods used in the laboratory to the point-of-care setting. In turn, these advances have now enabled health care providers and patients to make a choice about where testing is conducted ([Box 17.1](#)).

BOX 17.1 Environments Where Point-of-Care Testing Might Be Employed

Primary Care

Home
Community pharmacy
Health centers (general practice, primary care)
Workplace clinic
Physician's office and community clinic
Diagnostic and treatment center
Paramedical support vehicle (ambulance, helicopter, aircraft)

Secondary and Tertiary Care

Emergency room
Admissions unit
Ambulatory diagnostic and treatment center
Operating room
Intensive care unit
Ward
Outpatient clinic

BOX 17.2 Potential Advantages and Disadvantages of Point-of-Care Testing

Advantages

Reduced turnaround time for test results
Improved patient management; improved interaction between patient and caregiver
Improved patient morbidity and mortality
Reduction in the administrative work associated with test requesting and reporting
Reduced risk of errors
Reduction in clinic visits
Reduction in hospital admissions
Improved cost of care

Disadvantages

Increase in administrative work associated with training and certification of operators
Care giver required to perform test
Increased risk of errors if tests performed by untrained operators

Fig. 17.1 Schematic representation of the key steps in requesting, delivering, and using a diagnostic test result.

Clinical needs met by POCT can include more rapid clinical decision-making (especially in situations of clinical urgency), with the possibility of improved clinical outcomes. POCT can also reduce the complexity of the testing process—so-called process needs—which include improving the immediate patient/clinician/caregiver interaction, as well as expediting the patient journey, and improving the patient's experience and patient empowerment. The patient testing process is shown in Fig. 17.1, while the advantages and disadvantages of POCT are summarized in Box 17.2.

TECHNOLOGY

The technology used to measure **analytes** outside of the conventional laboratory setting has come about partly through the long-term trend of miniaturization—that is, reducing the size of electronic devices, as in the case of mobile phones. Advances in information and communications technologies have also played an important role. Starting with instruments to measure electrolytes, blood gases, and glucose, it is now

possible to measure many other analytes using increasingly smaller devices. Accompanying the process of miniaturization has been the development of dry, stable reagents that can be incorporated in disposable unit-dose devices. While the throughput of tests for these devices is low (e.g., typically <10 samples per hour depending on test type), the time required to produce the results is usually short (e.g., may vary from seconds for capillary blood glucose testing to several minutes for immunoassay based tests).

Required Features of Point-of-Care Testing Devices

As with any device, it is important that designers first consider the needs of users, and these depend to some extent on the clinical setting or application. Some simply stated but critical requirements are as follows:

1. Devices should be simple to use.
2. Reagents and consumables must be robust over extended periods of time.
3. Results from POCT devices should be concordant with established laboratory methods, and the analytical quality of results should be appropriate to the intended clinical purpose.
4. The device together with its associated reagents and consumables must be safe to use.

Design criteria become more specific for particular clinical settings. For example, criteria exist for devices designed for use in the developing world for sexually transmitted diseases (STDs), a major unmet medical need that is just beginning to be addressed effectively. Provided by the World Health Organization (WHO), the so-called ASSURED criteria are as follows:

- Affordable—for those at risk of infection
- Sensitive—minimal false negatives
- Specific—minimal false positives
- User-friendly—minimal steps to carry out test

TABLE 17.1 Classification of Types of Point-of-Care Testing (POCT) Instruments or Devices

Classes of Technology	Analytical Principles Used in the Classification	Example Analytes
Small handheld, single-use, POCT devices	Reflectance	Urine and blood chemistry
Small handheld, single-use, POCT devices with a monitoring device	Lateral-flow or flow-through immunoassays	Infectious disease agents, cardiac markers, hCG
	Reflectance	Glucose
	Electrochemistry	Glucose
	Reflectance	Blood chemistry
	Light scattering/optical motion	Coagulation
	Lateral-flow, flow-through, or solid phase immunoassays	Cardiac markers, drugs, CRP, allergy, and fertility tests
	Immunoturbidimetry	HbA1C, urine albumin
	Spectrophotometry	Blood chemistry
Larger cartridge-type and bench-top POCT devices	Electrochemistry	pH, blood gases, electrolytes, metabolites
	Fluorescence	pH, blood gases, electrolytes, metabolites
	Multiwavelength spectrophotometry	Hemoglobin species, bilirubin
	Time-resolved fluorescence	Cardiac markers, drugs, CRP
	Electrical impedance	Complete blood count
	Polymerase chain reaction	Bacteria and viruses
	Fluorescence, electrochemistry with PCR	Infectious agents
	Electrochemistry	pH, blood gases, electrolytes, metabolites

- Rapid and robust—short turnaround time (TAT) and no need for refrigerated storage
- Equipment-free—no complex equipment
- Delivered—to end users

Connectivity to information systems, including the patient health record, is a growing requirement in modern health care systems.

A more recent design challenge is the need to simultaneously measure multiple analytes in the same cartridge—so-called multiplexing. The Piccolo chemistry analyzer (Abaxis, Union City, CA) and blood gas or critical care analyzers are some of the relatively few examples of such technologies. The main benefit is the reduced overall time to result.

Design

There is a great diversity of devices being used for POCT (Table 17.1), the majority relying on technologies devised more than two decades ago. Many of the devices use the same analytical principles as those found in conventional laboratory analyzers, but newer technologies are starting to appear, some of which will be described.

Irrespective of the type of technology, all POCT devices should have several key components, which include (1) the operator interface, (2) bar code identification systems, (3) sample and reagent delivery mechanisms, (4) reaction cell, (5) sensors, (6) control and communications systems, and (7) data management and storage. The main objectives of the design are to (1) enable the required reaction to take place that allows measurement of the analyte of interest, (2) ensure reliable and stable performance of the device over a period of time, and (3) minimize the risk of operator error.

Operator Interface

The **operator interface** for a POCT device should (1) require minimal operator interaction; (2) guide the user through the

operation; (3) indicate whether any key steps have failed; and (4) allow identification of the (A) operator, (B) patient, and (C) test to be measured.

Advances in information technology (IT) and electronics have had a major impact on this area. Types of user interfaces include (1) keypads, (2) bar code readers, (3) printers, and (4) touch screens.

Bar Code Identification Systems

Many POCT devices incorporate bar code reading systems for a number of purposes. These include (1) identifying the reagent package to the system—whether it be a single-use disposable or a multiuse reagent pack, (2) incorporating factory calibration data, and in some cases, (3) programming the instrument to process a particular test or group of tests. Some POCT devices use magnetic strips as a way of storing similar information, such as lot-specific calibration data. Other functions of the bar code reader include the capability to identify both the operator and the patient sample to the system.

Sample Types and Sample Delivery

The vast majority of POCT devices use whole blood or urine specimens; in the case of blood, this commonly involves a capillary or finger-stick sample. In this way the sample can be introduced to the POCT device directly. Alternatively, a venous or arterial blood specimen can be collected and a small sample removed for POCT; in some cases the blood collection tube can be inserted directly into the POCT instrument.

Sample access and delivery to the actual sensing component of the strip, cassette, cartridge, or fluidic cell are also key processes that are prone to error. Ideally, following the addition of the sample, there should be no further need for operator intervention. Devices are now available that minimize the degree of interaction to the point where a closed tube simply

has to be placed in a holder and the instrument automatically performs all other functions.

Reaction Cell

Where the analytical reaction takes place varies from a simple porous pad to a microfluidic cartridge, or surface within a cartridge. Advances in **fluidics** and fabricating techniques have been critical to the development of POCT devices. As analytical reactions have increased in complexity, more reaction cells/zones have been added. Thus, in the case of molecular tests, different reaction zones may be required for DNA extraction, amplification, and probe detection. Another consideration in the design of reaction cells is to ensure that the requisite mixing of sample and reagents occur, which is critical when using very small volumes.

Sensors

Much of the development focus in POCT devices has been concerned with the advances in **sensor** design of which there are various types. A chemosensor is one where the analyte has an intrinsic property, such as electrochemical, that enables it to be detected without a **recognition element**. More commonly, chemosensors used in many POCT devices have a transducing element such as a chemical indicator or binding molecule that recognizes the analyte to be measured and produces a signal, usually electrical or optical. A biosensor is distinguished from a chemosensor by having a biological or biochemical component as the recognition element. Enzymes are the most common biological element used followed by antibodies; transduction typically is via an optical or electrical signal, although there is now an increasing use of antibody and nucleic acid recognition elements.

Control and Communications Systems

In even the smallest device, there is a control subsystem that coordinates all the other systems and ensures that the required processes for an analysis take place in the correct order. Operations that require control include (1) insertion or removal of the strip, cartridge, cassette, or reagent; (2) temperature control; (3) sample injection or aspiration; (4) sample detection; (5) reagent addition—especially in a fluidic-based system; (6) mixing; (7) timing of the detection process; (8) detection of measurement signal; and (9) waste removal. Fluid movement is often accomplished by mechanical means through pumps or centrifugation, and by fluidic properties, such as surface tension; the latter is often a critical element in the design of simple strip tests and in microfabricated systems.

Data Management and Storage

IT is crucial to POCT devices and may include rules-based assessment of internal quality control results, computing, and reporting of patient results. In some systems, data transfer and management take place when the meter or reader is linked to a small bench-top device called a docking station, but increasingly devices use wireless technology for communication. These and other devices include communication

protocols that allow data to be transferred to other data management systems, electronic medical records, and mobile computing devices.

Types of Existing Point-of-Care Testing Technology

POCT devices can be classified into small, handheld devices that often use qualitative or quantitative reagent strips (or similar technology with a reading device), and larger, bench-top devices that are often variants of ones used in conventional laboratories. This classification is somewhat arbitrary since there is no sharp demarcation. There are gradations in both size and internal complexity of devices, although differentiation can sometimes be made on the need for external power. The clear trend is toward devices becoming smaller and with greater functionality.

Small Handheld, Single Use Point-of-Care Testing Devices

Many POCT devices fall into this category, including (1) single- or multipad tests that are read visually, by reflectance photometry or electrochemically; (2) more complex pads that use light reflectance for measurement; and (3) fabricated cassettes or cartridges that incorporate methodologies such as immunochromatography and are used as immunosensors. All these devices are truly portable and for that reason their operational mode (i.e., proximity to the patient) differs from larger bench-top devices. For example, devices that require application of a whole blood sample such as glucose strips obviate the need for sample containers, labeling or transport, as compared with larger POCT instruments that may be some distance from the patient.

Single and multipad strip tests. These are relatively simple in construction and are composed of a pad of porous material, such as cellulose, that is impregnated with reagent and then dried. Samples are added to the device either by dipping (e.g., in urine analysis) or by spotting (e.g., in blood glucose analysis). In the latter case, there has been a gradual transition from optical to electrochemical detection, avoiding the need to wipe the strip to remove surplus blood prior to measurement. A critical operator factor when spotting the sample onto the pad is the need to cover the whole pad with the sample. In addition, because the reactions often do not proceed to completion, it is necessary for visually read tests to be timed between placing the sample on the pad and comparing the resulting color to a color chart. More complex pads are composed of several layers, the uppermost of which is a semipermeable membrane that prevents red cells from entering the matrix.

Immunostrips. These are biological sensors in which the recognition agent is an antibody that binds to the analyte. Detection of the binding event or signal **transducer** is usually via an optical mechanism, either reflectance or fluorescence spectrophotometry, although visual inspection has also been used. Immunosensors typically use solid phase technologies in conjunction with (1) flow-through, (2) lateral-flow, or (3) immunochromatography processes. In the flow-through

format, a heterogeneous immunoassay takes place in a porous matrix that acts as the solid phase and requires an additional reagent to wash and separate bound and unbound label. In lateral flow, the separation stage takes place as the sample passes along the porous matrix, and no additional wash solution is required. In all these different formats, uniform and predictable flow of the sample through or along the solid phase matrix is a major determinant of the reproducibility of the technique.

In a typical example of an immunostrip for cardiac troponin T (cTnT), the blood sample is added and first flows through a glass fiber fleece, which separates the plasma from whole blood. Simultaneously, two monoclonal anti-human cTnT antibodies, one conjugated to biotin and one labeled with gold particles as the signal antibody, bind to troponin T in the sample to form a sandwich complex. The antibody-troponin sandwich complex then flows in a lateral direction along the cellulose nitrate test strip until it reaches the capture zone, which contains streptavidin bound to a solid phase. The biotin in the antibody troponin complex binds to the streptavidin and immobilizes the complex. The complex is then visualized as a purple band by the gold particles attached to the signal antibody. The unreacted gold-labeled antibody moves farther down the strip, where it is captured by a zone containing a synthetic peptide consisting of the epitope of human cTnT and is visualized as a separate but similar colored band. The presence of this second band serves as an internal quality indicator because it shows that the sample has flowed along the test strip and the device has performed correctly.

While the majority of quantitative lateral flow immunoassay devices only measure a single analyte at a time, some can measure a panel of analytes, such as cardiac markers, fertility tests, and drugs of abuse.

Small Handheld, Single Use Point-of-Care Testing Devices With a Monitoring Device

Glucose Measurement. In clinical practice, capillary glucose measurement is the most common POCT application. These devices are biosensors because they all use an enzyme as the recognition agent—glucose oxidase (GO), hexokinase (HK), or glucose dehydrogenase (GDH)—with photometric (reflectance) or, now increasingly, electrochemical detection.

Modern glucose strips use *thick-film* technology with several layers, each having a specific function. These are shown diagrammatically for a reflectance-based strip in Fig. 17.2. When blood is added to a strip, both water and glucose pass into the analytical layer. For some photometric systems, erythrocytes are excluded by a spreading or separating layer that contains various components, including glass fibers, fleeces, membranes, and special latex formulations. In photometric systems, a spreading layer is also important for the fast, homogeneous distribution of the sample. In contrast, electrochemical strips use systems that rely on capillary action to move the blood sample over the electrodes. The support layer is usually a thin plastic material that in the case of reflectance-based strips may also have reflective properties.

Fig. 17.2 Schematic diagram of the components that make up a typical reflectance-based glucose strip.

Additional reflectance properties have been achieved through the inclusion of substances such as titanium oxide, barium sulphate, and zinc oxide.

Glucose strips are produced in large batches, and after extensive quality assurance procedures by the manufacturer, each batch is given a code that is stored in a magnetic strip on the underside of each test strip. This code describes the performance of the batch, including the calibrating relationship between the photometric or electrochemical signal and the concentration of glucose. More recently, electrochemical glucose strips that do not require coding have become more commonplace. These are composed of an Ag-AgCl reference electrode and a carbon-based active electrode, both manufactured using screen printing technology with ferrocene or its derivatives contained in the printing ink. The conversion of glucose is accompanied by the reduction of ferrocene and the release of electrons. Continuing innovations have also facilitated the production of smaller meters, nonwipe strips, less need to clean instrument optics, more rapid results, and smaller sample volumes.

Although electrochemical systems have enabled the design of strips that are less subject to interferences, problems still persist. Strips that use GO are more substrate specific but are affected by oxygen tension, with high PO_2 values leading to falsely low results. Blood oxygen tension does not affect GDH based strips, but GDH strips that use the pyrroloquinolinequinone form of the enzyme are subject to interference by maltose. Excessive concentrations of the latter, such as in some parenteral solutions, can cause falsely high glucose results, masking hypoglycemia, and several deaths have been attributed to these errors. Hematocrit is another important interference, the effects of which have been reduced in newer strip designs.

Fig. 17.3 Epoc test card for blood gas analysis. (Courtesy Alere.)

INR Measurement. Another common meter-type device used by patients at home and by health care professionals in clinics are those employed to monitor warfarin (Coumadin) therapy and measure prothrombin time (reported as INR levels). First devised some two decades ago, a number of different technologies have been developed to measure INR at point of care, including optical and electrochemical detection. Innovation has been applied both to the strip, where a drop of blood is placed, and to the meter into which the strip is placed. In the HemoSense device (Alere, Waltham, MA), clotting is detected by change in impedance, while in a Roche device (Roche Diagnostics, Basel, Switzerland), a change in current is detected. Both devices incorporate QC systems that are activated when a patient sample is placed on the strip. In the case of HemoSense, the strip has three channels: one for the patient test and the other two for different concentrations of internal QC material.

Handheld integrated cartridge technology. The prime example of this type of technology is the i-STAT analyzer (Abbott Point-of-Care, Princeton, NJ), a handheld device originally designed to measure blood gases but now with a considerably extended menu that includes electrolytes, glucose, creatinine, coagulation parameters, and cardiac markers. In contrast to the thick-film technology described above, the single-use sensors are constructed using *thin-film* technology. The latter involves microlithographic processes to deposit thin layers of 1 to 10 μm (as opposed to 10 to 50 μm layers in thick film technology), similar to the construction of computer chips and other silicon-based devices. Each single use i-STAT cartridge contains an array of electrochemical sensors for a set of particular analytes, and it is operated in conjunction with a handheld reading device. Because the sensor layer is very thin, analytes permeate to this layer quickly, and the sensor

cartridge, once it reaches room temperature (if it has been refrigerated), can be used immediately. This is an advantage over some thick-film sensors that require an equilibration or “wet-up” time before they are used.

A disadvantage of thin-film technology is that manufacturing costs are high due to the need for special clean air facilities. Thus more recent technology to measure blood gases and related parameters utilizes less costly, so-called smart card technology. An example is the Epoc system (Epocal, Ottawa, Canada), which is used in conjunction with a handheld analyzer to provide a range of critical care tests, including immunoassay measurement. Fig. 17.3 shows two views of the Epoc test card, which is manufactured on a 35 mm tape on reel format; on the right is the top view of the test card showing the sample entry port, the sealed calibrator reservoir, and the sensor module at the top; on the left is the bottom view of the card with the sensor module, where measurements take place, and below this are details of the test panel.

Larger Cartridge Type and Bench-Top Point-of-Care Testing Devices

This section includes a wide range of devices that are all quantitative, not handheld but varying considerably in size. The smaller ones typically incorporate small, compact detectors, such as a charge-coupled device (CCD) camera that is a multichannel light detector, similar to a photomultiplier tube in a spectrophotometer. This type of technology enables quantitative measurements of lateral-flow immunoassay strips and is incorporated in the many different POCT devices available on the market.

Cartridge-type devices. A number of single-use, quantitative POCT devices are available that employ a cassette or cartridge design rather than lateral-flow strips. Several

Fig. 17.4 Schematic diagram of the Bayer DCA 2000 HbA1C immunoassay cartridge. (Courtesy Siemens Medical Diagnostics.)

cassette-based systems have been developed for the measurement of hemoglobin. In one such system, red cells are lysed in a minicuvet, hemoglobin converted to methemoglobin, and the methemoglobin measured at 570 nm; turbidity is corrected for by an additional measurement at 880 nm.

Another type of cartridge design uses a light-scattering immunoassay to measure glycated hemoglobin, together with a photometric assay for total hemoglobin. The cartridge is a relatively complex structure that contains all the reagents required for the immunoassay, as well as lysing reagents and potassium ferricyanide reagent for measurement of total hemoglobin (Fig. 17.4). Agglutination takes place between the latex bound antibody and a synthetic polymer that contains the immunoreactive portion of HbA1C that leads to increased scattering of light. Addition of HbA1C in the patient sample reduces the agglutination by competing for the latex bound antibody, and the reduction in light scattering is proportional to the concentration of HbA1C.

Measurement takes place when the cartridge is placed into a temperature-controlled reader, and the analytical performance of the Siemens DCA device (Siemens Healthcare GmbH, Erlangen, Germany) is sufficient for quantitative monitoring of glycemic control, and can also be used for measurement of urinary albumin and creatinine. Following placement into the instrument, the analysis proceeds without further involvement of the operator. The most recent of these types of instruments is also considerably smaller, and that trend is likely to continue.

Multianalyte desktop analyzers. A typical example of these is the Piccolo (Abaxis), which can measure a wider range of general chemistry analytes on a very small sample volume. It uses a small disposable rotor that contains all the required reagents and diluents to perform a battery of related tests such as liver function tests.

The Radiometer AQT 90 (Radiometer Medical, DK-2700, Bronshøj, Denmark) bench-top, random access immunoassay analyzer utilizes a proprietary dry-chemistry concept and a detection method based on europium nonenhanced

time-resolved fluorescence (TRF) technology. The europium-based chelates have certain natural advantages that allow sensitive and rapid detection methods. Analysis takes place in a small reagent cup on which are immobilized biotinylated capture antibodies, as well as streptavidin and europium-labeled tracer antibodies. Following addition of the patient sample and incubation, an antibody-antigen-antibody “sandwich” complex is formed, and after washing and drying, the europium response to excitation light is measured, the amount of which is directly proportional to the antigen present. The AQT 90 also has a unique, walk-away, closed-tube sampling device from which the instrument dispenses a sample into a cup containing dried reagents including antibodies to the analytes of interest and europium lanthanide chelate as the signal reagent. The menu includes troponin, brain natriuretic peptide (BNP), D-dimer, beta human chorionic gonadotropin (hCG), and C-reactive protein (CRP).

Critical care analyzers. These remain the most commonly used type of POCT bench-top analyzers; the expanded menu of analytes allows use in many clinical areas. These devices use the same type of thick-film sensors or electrodes in strips, as described above, but in this case the sensors are reusable. They are manufactured from thick films of paste and inks using screen-printing techniques to produce individual or multiple sensors for metabolites, blood gases, and electrolytes. Further details of the analytical principles behind these sensor technologies can be found in Chapter 10 of this textbook. The sensors have been incorporated with reagents and calibrators into a single cartridge or pack, which is placed in the body of a small- to medium-sized, portable critical care analyzer. Each pack contains reagents sufficient to test a certain number of samples during a specific time period, after which it is relatively simple to replace. An example of such a device is the GEM Premier 4000 (Instrumentation Laboratory, Bedford, MA; Fig. 17.5).

Other key developments in critical care instruments include liquid calibration systems that use a combination of aqueous base solutions and conductance measurements to calibrate the pH and PCO_2 electrodes, with oxygen being calibrated with an oxygen-free solution and room air. In addition, automated QC packages are integrated into these instruments to ensure that QC samples are analyzed at regular intervals. These comprise packs or bottles of QC material that are contained within the instrument and sampled at predetermined intervals with on-board software, interpreting the results and generating alerts, if necessary. Box 17.3 shows the various features that are incorporated into a critical care analyzer that contribute to its ease of use and reduce the potential for errors.

Hematologic and immunologic analyzers. Small bench-top devices are now available to perform hematologic and immunologic analysis at point of care. Again, they are often scaled-down versions of laboratory instruments but have been reduced in complexity, thus reducing the risk of operator error by non-technically trained staff. The range of hematologic instruments include those that measure just hemoglobin

Fig. 17.5 Schematic diagram of the components and patient sample fluidic pathways of the GEM Premier 3000 critical care analyzer. (Courtesy Instrumentation Laboratory.)

BOX 17.3 Features of Critical Care Analyzers That Contribute to Ease-of-Use and Reduce the Risk of Errors

- Long-life, maintenance-free electrodes or disposable sensor packs
- Touch screens as the user interface
- Software that can demand user and patient identification
- Built-in bar code scanners
- Sample aspiration instead of injection
- Reduced sample sizes
- Clot detection within analysis chamber
- Sample detection to prevent short samples
- Liquid calibration systems instead of gas bottles
- Automated calibrations
- Automated quality control sampling
- Sophisticated QC programs including interpretation of data
- Connectivity to information systems allowing remote monitoring and control
- Built-in videos for training purposes

and white cell counts to the Sysmex pocH-100i (Sysmex, Lincolnshire, IL), which can measure up to 17 parameters.

Another relatively new product is the PIMA flow cytometer device (Alere) that can be used for measurement of T-helper cells, or CD4 counts. The PIMA uses the same imaging and cell counting technology employed in laboratory instruments but redesigned into a smaller, more compact instrument, which is simple to operate. Following mixing of the sample with the reagents and incubation, fluorescence is measured in the stained sample by a CCD camera and the results are displayed on the screen.

Newer and Emerging Point-of-Care Testing Technologies

Many laboratory technologies have been refined and packaged into smaller devices, and in many cases, there has been an improvement in analytical performance and a reduced risk of error. That trend in incremental improvements will continue, because no device is risk-free and in some cases there remains a need for better analytical performance. In addition,

Fig. 17.6 Schematic diagram of a microfluidic card employing a molecular test for *Chlamydia trachomatis*. (Courtesy Atlas Genetics, Trowbridge, UK.)

the search for fundamentally different technologies continues because there are known limitations to existing technologies. For example, lateral flow strip technology continues to dominate the POCT market, but they have a number of limitations, including inadequate sensitivity and difficulty with multiplexing or measurement of more than two or three analytes on the same strip. An alternative measurement concept for the future is the so-called Lab on a Chip (LOC), also referred to as a microchip, adapted from the microelectronics industry through techniques of miniaturization and microfabrication. LOC devices have been defined as ones that perform analysis at microscopic scales (i.e., 1 to 500 μm) and incorporate microfilters, microchannels, microarrays, micropumps, microvalves, and bioelectronics chips.

Despite the continuing advances taking place in silicon chip manufacturing, these advances have not as yet translated into the development of many LOC devices for point-of-care use. One such LOC device is the Cepheid GeneXpert system (Cepheid, Sunnyvale, CA). This bench-top device can perform real-time quantitative polymerase chain reaction (PCR) in approximately 90 minutes with minimal operator interaction, thus enabling the potential to perform rapid molecular testing in situations where the need for results is urgent. Until recently the only technology available for point-of-care infectious disease testing such as influenza has been lateral flow strips with their previously described problems of limited sensitivity, which are overcome by PCR related techniques such as the Cepheid instrument. The system uses single-use cartridges that each contain multiple chambers to hold the sample, various purification and elution buffers, and all the PCR reagents, including enzymes; in addition, all waste is

retained within the cartridge. Through a series of valves in the syringe, the sample is moved through the various stages of the PCR process using the reagents stored in the cartridge, and culminating in real-time detection of the amplified products.

Rapid molecular and other types of testing are also possible using technology developed by Atlas Genetics (Atlas Genetics, Trowbridge, Wilts, UK). The system comprises a test-specific disposable cartridge, containing all the necessary reagents to perform the test and shown in Fig. 17.6. Following addition of the specimen into the sample well of the cartridge and insertion of the cartridge into the Atlas io reader, the test is performed under complete instrument control with no further user input required. After sample addition, lysis of sample and internal control material, the mixture is pumped to the capture column where DNA is captured. Following PCR, the amplified mixture moves to the detection chambers for electrochemical measurement. The system is capable of multiplexing by virtue of a number of independent fluidic channels and the opportunity to use a number of electrochemical labels.

Informatics and Point-of-Care Testing

Most analytical devices used in clinical laboratories are directly linked or connected via an electronic interface to a laboratory information system (LIS). In this progression, many different informatics functions are used, including the electronic transfer of data from the analyzers to the LIS and ultimately into a patient's electronic medical record. This provides health care professionals with quick, accurate, and appropriate access to the patient's medical history and clinical information.

Considerable effort has been expended to incorporate these same processes into POCT devices because of the vital

Fig. 17.7 Schematic diagram of a point-of-care testing (POCT) network showing the relationships between the user, POCT device, other health information systems, and the patient's caregiver. *INR*, International normalized ratio. (Courtesy R. Tirimacco, ICCNET.)

importance of capturing analytical data in a patient's medical record in order to avoid the errors associated with manual transcription of data. Thus newer POCT devices have addressed this problem by incorporating the prerequisite hardware and software into their design, and in the last decade so-called connectivity standards have also been introduced, which facilitate linking devices to information management systems. Adherence to these connectivity standards ensures that POCT devices meet critical user requirements, such as (1) bi-directionality, (2) device connection commonality, (3) commercial software interoperability, (4) security, and (5) QC and/or regulatory compliance.

Improved connectivity has enabled two major trends. First, and primarily due to demand from those responsible for the management of POCT, there has been the development of a range of commercial and specialized products for data management of POCT results with software devoted to ensuring compliance with procedures and managing data. These systems offer a range of features and benefits that include the ability of central laboratories to both monitor and remotely control their instruments in locations outside of the main laboratory.

The second trend is that connectivity standards, together with less expensive network technology and widespread access to the internet and smart mobile phones, have provided the capability to establish POCT networks across major secondary and tertiary care institutions and, perhaps more importantly, in the community or primary care where POCT has the potential to make a much bigger impact than in the

hospital setting. The structure of such a typical community POCT network is shown in Fig. 17.7.

The most important benefit of connectivity remains that of facilitating the transfer and capture of patient POCT and quality-related data into permanent medical records. Additional benefits include that of providing alerts of abnormal results, particularly those that may be critical. However, the increasing ability to interface devices more easily to other information systems should also enable the development of applications, which add value to patient data such as the use of decision support software to assist with interpretation and clinical decision-making. One such example is the use of dosing software in combination with POCT INR measurements to manage warfarin treatment.

Points to remember—Point-of-Care Testing Technology

- POCT devices need to be simple to use and the reagents and consumables need to be robust over extended periods of time.
- Analytical results need to have an analytical quality appropriate for the clinical requirement.
- Glucose strips and lateral flow immunosensors remain the most common type of POCT technology.
- Newer technologies using molecular techniques are now starting to emerge.
- All devices should either have a means of data storage or be interfaced to an information system so that data can be stored, transmitted, and recalled.

BOX 17.4 Assessing the Need for a Point-of-Care Testing (POCT) Service

Which tests are required?
 What is the turnaround time required?
 What clinical question is being asked when requesting this test?
 What clinical decision is likely to be made upon receipt of the result?
 What action is likely to be taken upon receipt of the result?
 What outcome should be expected from the action taken?
 Why isn't the laboratory able to deliver the required service?
 Will POCT provide the required accuracy and precision of result?
 Are there staff available to perform the test?
 Are there adequate facilities to perform the test and store the equipment and reagents?
 Will you abide by the organization's POCT policy?
 Are there operational benefits to this POCT strategy?
 Are there economic benefits to this POCT strategy?
 Will a change in practice be required to deliver these benefits?
 Is it feasible to deliver the change in practices that might be required?

QUALITY MANAGEMENT

Management and maintenance of a POCT service requires planning, oversight, inventory control, and assurance of the reliability of test results through adequate training and QC. Several guidelines document these requirements, based on the ISO standard 22870 ("Point-of-Care Testing [POCT]—Requirements for Quality and Competence"), and are available from various professional laboratory organizations.

Establishment of Need

The decision to implement a POCT service requires (1) establishment of the unmet need, (clinical, operational, or economic); (2) critical appraisal of the evidence supporting the claimed clinical, operational, and economic benefits; and (3) examination of the costs and changes in the clinical process involved. Addressing the questions listed in [Box 17.4](#) is useful for establishing the requirement for a POCT service.

When organizing and implementing a POCT service, it is important to consult with all the stakeholders, by establishing a POCT coordinating committee. Membership should include representatives of those who use the service and those who deliver the service, together with a representative of the organization's management team. The users may include (1) physicians, (2) physician assistants, (3) family nurse practitioners, (4) nurses, (5) other health care providers, and (6) patients. Typically a laboratory professional will chair such a committee, and it is also recommended that the committee report to the medical director of the hospital or other care provider organization. The work of the committee should be governed by the organization's policy on POCT.

Health and Safety Procedures**Bibliography****Point-of-Care Testing Policy and Accountability**

Implementation of a POCT service requires a POCT policy that establishes all of the procedures required to ensure the delivery of a high-quality service, together with the responsibility and accountability of all staff associated with the POCT. This may be (1) part of the organization's total **quality management** system, or (2) part of its clinical governance policy, and will be required for **accreditation** purposes. The elements of a POCT policy are listed in [Box 17.5](#).

Equipment Procurement and Evaluation

After identifying a requirement for POCT, developing a POCT policy, and establishing a coordinating committee, the next stage in the process is equipment procurement. This involves identifying candidate POCT equipment having the prerequisite analytical and operational capabilities to meet the clinical requirements of the POCT service. A CLSI protocol (Clinical Laboratory Standards Institute, Document POCT09-P. Selection Criteria for Point of Care Testing Devices) describes

BOX 17.6 The Main Elements of a Point-of-Care Testing Training Program

the features of the evaluation process, and further guidance can be sought from other evaluations described in the literature. In addition, the educational and certification requirements of the device operator also have to be identified, and the potential for operator error determined. Independent validation of these analytical and operational characteristics is obtained from (1) the manufacturer, (2) published evaluations performed by government agencies, (3) reports in the peer-reviewed literature, and (4) discussions with colleagues.

Training, Competency, and Certification

Many of the agencies involved in the regulation of health care delivery now require that all personnel associated with the delivery of diagnostic test results demonstrate their competence, and this applies equally to operators of POCT equipment. The elements of a training program are listed in Box 17.6. Clearly the extent of this program will, to a certain extent, depend on how well the complexity of the analytical method has been engineered to minimize operator requirements. In practice, such a program is tailored to meet the needs of the individual and the organization.

Training may include formal presentations, self-directed learning, or computer-aided learning. It is important to document the satisfactory completion of training, and that the individual has been tested and found competent, with a combination of questions probing the understanding and practical demonstration of the skills gained. The latter is achieved by performing tests on a series of QC materials and repeat testing of patient samples that have recently been analyzed in the laboratory or on another device—so-called parallel testing.

Competence on a long-term basis is maintained through regular practice of skills and continuing education, and it is

important to build these features into any POCT program. Regular review of performance in QC and quality assurance programs will provide a means of overseeing the competence of operators. The error log may also highlight when problems are arising. However, it is important to encourage an open approach to the assessment of competence so that operators themselves seek help if they believe that problems are occurring.

Quality Control, Quality Assurance, and Audit

Quality control, external quality assurance (EQA), or proficiency programs and audits provide a formal means of monitoring the quality of a service. The QC program gives a relatively short-term view and typically compares the current performance of a device with prior analyses. EQA is a more comprehensive process that includes comparing testing performance of different sites and/or different pieces of equipment or methods. Audit measures the performance of all aspects of the testing process against predetermined standards. However, the foundation to ensuring good quality remains a successful training and competency scheme.

Classically quantitative QC involves the analysis of a sample for which the analyte concentration is known, and the mean and range of acceptable results is quoted for the method used. There are several challenges to the classical approach with POCT. The first concern is the frequency of testing—should a QC sample be analyzed every time that (1) a sample is analyzed, (2) a new operator uses the system, (3) a new lot number of reagents is used, or (4) the system is recalibrated? There is no consistent agreement on the correct approach, and one probably has to be guided by the reproducibility and overall analytical performance of the system, but it should never be less than what is recommended by the manufacturer or what is necessary to meet regulatory requirements.

For single-use POCT disposable devices, the above strategy does not completely monitor the quality of the test system. For example, when conventional QC material is analyzed on a unit-use or single-test POCT system, only that testing unit is monitored. Under these circumstances, there is greater dependence placed on the manufacturing reproducibility of the devices to ensure a good quality service.

There are also other QC approaches, but many do not test the whole process. For example, the use of a plastic surrogate reflectance pad as a QC sample will only test the performance of the reflectance meter and so on. Similarly, some forms of electronic internal QC also do not test the sampling technique, but simply the functionality of the cassette and the docking station. As with conventional QC, any electronic process checks should not be less than those recommended by the manufacturer.

EQA, or proficiency testing, is a systematic approach to QC monitoring in which samples are analyzed by one or more laboratories to determine the capability of each participant. In this approach, the operator has no knowledge of the analyte concentration, and therefore it is considered closer to a “real testing situation.” The results are transmitted to a

central authority, which then prepares a report and returns a copy to each participating laboratory. More details of quality management as applied to POCT can be found in [Chapter 7](#) of this textbook.

Maintenance and Inventory Control

The implementation and maintenance of a POCT service require that a supply of devices and associated consumables be maintained at all times and that a formal program for doing so is employed. The key points in this process are to (1) adhere to the recommended storage conditions, (2) be aware of the stated shelf life of the consumables, and (3) ensure that stocks are released in time for any preanalytical preparation to be accommodated (e.g., thawing).

Clear guidelines should be available from the manufacturer and should be adhered to rigorously. Issues that usually require particular vigilance include expiration dates, biocontamination, electrical safety, maintenance of optics, and inadvertent use of inappropriate consumables.

Documentation

It is critically important to keep an accurate record of the (1) test request, (2) result, and (3) action taken, in the medical record. Some of the issues concerning documentation are now being resolved with the advent of the patient electronic record, electronic requesting, and better connectivity of POCT instrumentation to information systems and the patient record.

Accreditation and Regulation of Point-of-Care Testing

Regulatory and/or accrediting bodies of medical laboratories generally require compliance to minimum standards, and this applies equally to POCT services. Thus the Clinical Laboratory Improvement Amendments of 1988 (CLIA) legislation in the United States stipulates that all POCT must meet certain minimum standards. In the United States, the Centers for Medicare and Medicaid Services, the Joint Commission on Accreditation of Healthcare Organizations, and the College of American Pathologists are among those responsible for inspecting sites, and each is committed to ensuring compliance with testing regulations for POCT.

POINTS TO REMEMBER—QUALITY MANAGEMENT

- Any point-of-care testing (POCT) service should be based on satisfying a documented clinical or operational need.
- A POCT policy agreed by all stakeholders should determine how the service is run within an institution.
- All POCT equipment should be evaluated by those responsible for the service.
- Training and assessment of competency of POCT users is essential since many will not be trained in laboratory science.
- POCT needs to be accredited to the same levels as the laboratory.

EVIDENCE OF EFFECTIVENESS

The objective of employing POCT is to enable clinical decisions to be made at the time of the consultation with the patient, where the decisions may relate to screening, diagnosis, treatment, or monitoring. The outcomes of these decisions should lead to clinical, operational, and/or economic benefits if implementation is to be considered. Typically those involved in the management decisions to implement POCT will look for evidence of clinical and cost **effectiveness**; those involved in implementation will, in addition, look for evidence of operational effectiveness, as that evidence will inform the implementation plan. It follows therefore that the evidence of effectiveness is employed in business cases proposing the adoption of POCT, and that it informs the implementation plan. The needs of all stakeholders involved in delivering the care package must be addressed. This can be challenging, as stakeholder perspectives may differ across a care pathway, for example, the current desire to shift care closer to home may have an adverse impact on the revenue received by the hospital.

Clinical Effectiveness

The core outcome measures of clinical effectiveness are mortality and morbidity. Surrogate or intermediate outcome measures are generally used for evidence of effectiveness in both the generation of evidence, as well as in performance management and audit. Some examples of outcome measures are given in [Table 17.2](#). The generation of evidence of clinical effectiveness in the field of diagnostics including POCT is challenging, primarily because (1) the timely delivery of a result in itself does not lead to improved outcomes (i.e., outcomes are dependent on the clinical management decision based on the test result), (2) variability can occur with both the decisions made and the action taken on receipt of the result, and (3) it is difficult to design studies that minimize the generally accepted risks of introducing bias (e.g., operator bias; see [Chapter 2](#)).

Examples of tests where there is good evidence for the clinical effectiveness of POCT include (1) rapid diagnosis of *Chlamydia* infection, (2) managing warfarin treatment with INR self-monitoring, (3) ruling out a diagnosis of deep vein thrombosis, and (4) managing patients with diabetes using HbA1C.

Cost-Effectiveness

Economic assessment is becoming more important because of the growing debate around “value-for-money” in health care, and consequently health care economics is seen as an integral part of evidence-based practice. An economic assessment of POCT should ask the question: What are the complete consequences and costs of using POCT compared with testing done in the laboratory? The consequences would include any operational changes involved with introducing POCT—particularly in the clinical setting, in addition to the impact on clinical outcomes. The reality is that relatively few economic assessments have been conducted in this way for laboratory tests and even fewer for POCT.

TABLE 17.2 Outcome Measures That Can Be Used to Assess Point-of-Care Testing Technologies

OUTCOME MEASURE			
Clinical	Process	Application	Test
Reduce antibiotic use	Reduce the need for laboratory tests	Rule out UTI	Urinalysis
Early detection of renal disease	Advise the patient at the clinic visit	Rule out albuminuria	Urine albumin creatinine ratio
Faster and earlier diagnosis	Reduced clinic visits Use of echocardiography	Rule out a diagnosis of heart failure	Natriuretic peptide
Reduced complication rate	Reduced nonattendance at the clinic Reduced clinic visits	Screening for infection	<i>Chlamydia</i>
Increased period within the therapeutic window	Reduced clinic visit Reduced hospitalization	Self-monitoring Self-dose adjustment	INR
Reduced complication rate			
Improved glycemic control indicated by HbA1C	Reduced clinic visits	Primary care management of diabetes	HbA1C in primary care
Faster triage to therapeutic intervention	Reduced length of stay in ED	Rule out acute coronary syndrome	Troponin I or T in ED
Faster diagnosis and treatment	Reduced clinic visits	Rule out DVT	D-dimer in primary care

DVT, Deep venous thrombosis; ED, emergency department; INR, international normalized ratio; UTI, urinary tract infection.

Instead of robust economic studies, there has been a focus in the past on simplistic comparisons of the cost of POCT technology to that used in the central laboratory without any consideration of the patient outcomes from using the tests. Thus many studies in the literature are of the cost minimization type and not surprisingly have shown that POCT is more expensive than the central laboratory, where economies of scale can deliver obvious efficiencies. However, this situation is changing to one that moves beyond a comparison of testing costs to one that includes assessment of the complete process of patient care and identification of the economic outcomes that can be achieved with POCT. Some of the economic benefits may result from a clinical impact upon the patient, but others may be operational benefits such as more rapid treatment, or reduction in length of stay.

POINTS TO REMEMBER—EFFECTIVENESS OF POINT-OF-CARE TESTING

- Point-of-care testing (POCT) may offer increased operational efficiency, for example, more rapid patient triage in emergency department.
- POCT may be associated with improved clinical outcomes, for example, reduced morbidity and mortality for home INR monitoring of coumadin treatment.
- POCT may offer increased patient accessibility and convenience, for example, testing and treatment in one visit for sexually transmitted diseases.

Consideration of the cost effectiveness must examine the impact of POCT on the entire care pathway, including patient outcomes.

REVIEW QUESTIONS

- Which of the following statements best describes the value of point-of-care testing (POCT)?
 - Testing performed outside of the laboratory
 - Testing performed at the bedside
 - Testing that enables the clinician or caregiver to make a decision at the time the clinical problem arises
 - Testing near to the patient
- The benefits of using POCT are best assessed by:
 - comparing the analytical results of the device with those obtained by the central laboratory.
 - performing a study of clinical and cost effectiveness.
 - assessing the performance of the device in an external quality assurance program.
 - asking the patients what they think.
- The technical performance of a POCT device is best assessed by:
 - comparing the results obtained by the person(s) who will be operating the device in the intended setting.
 - reviewing the manufacturer's literature.
 - testing the device in the laboratory.
 - looking for information on the Internet.
- Quality control of POCT for lateral flow strips read with a reflectance meter is best achieved by:
 - analysis of a designated QC specimen on at least one occasion in each shift.
 - use of the reflectance control strip supplied by the manufacturer.

- C. comparison of analysis of a specimen using the POCT with the results from sending the same specimen to the laboratory.
 - D. analysis of an aqueous solution prepared for the purpose.
 - E. reliance on the manufacturer to provide a quality controlled product.
- 5. The first step to be considered in the implementation of a POCT solution is:
 - A. the analytical imprecision of the POCT device.
 - B. the analytical bias of the POCT device.
 - C. the unmet clinical need.
 - D. the cost of each test.

Amino Acids, Peptides, and Proteins

Dennis J. Dietzen

OBJECTIVES

1. Define the following:
 - Acute-phase response
 - Bence-Jones proteins
 - Complement
 - Essential amino acid
 - Immunoglobulin
 - Isoelectric point
 - Paraprotein
 - Peptide bond
2. Diagram and describe the basic chemical structure of an amino acid.
3. Diagram the formation of a peptide bond from two adjacent amino acids.
4. Describe amino acid and protein analyses, including specimen requirements and quantitative analytical techniques.
5. Describe how amino acid carbon contributes to energy production.
6. Match the peptide(s) to the physiologic function:

Peptide:

 - Hepcidin
 - Natriuretic peptides
 - Angiotensins
 - Vasopressin

Function:

 - Promote Na retention and increased blood pressure
 - Inhibit iron mobilization
 - Promote water retention in collecting duct
 - Promote Na and water excretion
7. Explain the principle of serum protein electrophoresis, including a description of staining methods, and immunofixation.
8. Compare plasma and serum with regard to protein concentration.
9. List the acute-phase response proteins and the negative acute-phase response proteins.
10. List the various classes of protease molecules and representative members of each class.
11. List the various protein posttranslational modifications, and cite specific examples of proteins modified by each of the modifications.
12. Discuss the complement proteins, including their clinical significance, abundance, pathway involvement, and disease associations.
13. List the immunoglobulin classes. Describe their biochemistry, function, and clinical significance, and explain how they are affected by disease.
14. Discuss primary, secondary, tertiary, and quaternary protein structure.
15. Explain the presence of protein in cerebral spinal fluid (CSF) and the significance of increased CSF protein.

KEY WORDS AND DEFINITIONS

Acute-phase response Body's response to injury or inflammation.

Amino acid An organic compound containing both amino ($-\text{NH}_2$) and carboxyl ($-\text{COOH}$) functional groups.

Aminoaciduria An excess of amino acids in the urine.

Bence-Jones proteins Small light chains of immunoglobulin found in the urine.

Complement system Complex system of proteins found in blood that combines with antibodies to destroy pathogenic bacteria and other foreign cells.

Essential amino acids Amino acids that are not synthesized by humans and therefore are essential dietary constituents for maintaining health or growth.

Immunoglobulins A family of proteins also known as *antibodies* that contain highly specific antigen-binding

sites consisting of two identical heavy (H) chains encoded on chromosome 14 and two identical light (L) chains encoded on chromosome 2.

Isoelectric focusing An equilibrium technique that is used to separate charge variants of proteins and is applied to the analysis of certain genetic variants of proteins.

Kwashiorkor A form of protein-energy malnutrition produced by severe protein deficiency.

Marasmus A form of protein-energy malnutrition predominantly due to prolonged severe caloric deficit.

Monoclonal gammopathy of undetermined significance (MGUS) A condition in which a paraprotein is found in an individual's blood.

Multiple myeloma A cancer in which antibody-producing plasma cells grow in an uncontrolled and malignant manner.

Paraprotein A monoclonal immunoglobulin produced in excessive amounts in disorders such as multiple myeloma.

Peptide A compound consisting of two or more amino acids linked in a chain via peptide bonds.

Peptide bond The amide bond formed between the carboxyl group of one amino acid and the amino group of another.

Protein A polymer of amino acids linked by peptide bonds with a specific sequence that folds into a defined structure; any of a group of complex organic compounds that contain carbon, hydrogen, oxygen, nitrogen, and usually sulfur (the characteristic element being nitrogen).

Proteome The total complement of proteins expressed by the genetic material of an organism under a given set of environmental conditions.

Amino acids, peptides, and proteins are crucial for virtually all biologic processes. **Amino acids** serve as structural subunits of peptides and proteins but also play diverse roles in metabolism, neurotransmission, and intercellular signaling. **Peptides** serve as autocrine and endocrine signaling molecules that control appetite, vascular tone, and electrolyte homeostasis, as well as carbohydrate and mineral metabolism. **Proteins**, longer peptide chains with molecular mass typically greater than approximately 6000 Da, serve as (1) intracellular and extracellular structural components, (2) biologic catalysts, (3) mediators of contractility and motility, (4) agents of molecular assembly, (5) ion channels and pumps, (6) molecular transporters, (7) mediators of immunity, and (8) components of intracellular and intercellular signaling networks.

The human genome contains more than 20,000 open reading frames that encode proteins. The structural and functional complexity of these proteins is enhanced by alternative splicing of messenger RNA (mRNA), somatic recombination, mutation, proteolytic processing, and posttranslational modification. The **proteome** represents the complete set of proteins in an organism or compartment of an organism such as the plasma space. Diagnostic exploitation of the proteome promises to improve the detection and treatment of many pathologic conditions—most notably cancer.

This chapter begins with a discussion of the chemistry, metabolism, and analysis of amino acids. Discussion of the peptide bond and methods for measuring peptides follows. The protein narrative begins with an account of protein structure and the role of co- and posttranslational modifications in protein function. Important constituents of the proteome in various body fluids are then defined followed lastly by a description of methods for specific and global assessment of the proteins for clinical purposes.

AMINO ACIDS

Amino acids were likely among the first organic molecules to emerge from the mix of methane, hydrogen, ammonia, and water in earth's primordial atmosphere. Only 20 of the hundreds of known amino acids account for the vast majority of residues that make up human proteins. Their structure and molecular properties are summarized in Table 18.1. These 20, along with dozens of non-protein-forming amino acids, are critical to the form and function of the human body. Disrupted amino acid metabolism is not surprisingly associated with a multitude of pathologic processes.

Basic Biochemistry

Amino acids are organic compounds containing both an amino group ($-\text{NH}_2$) and a carboxyl group ($-\text{COOH}$), or another acidic group such as a sulfonate group ($-\text{SO}_3$). In a majority of biologically relevant amino acids, the amine moiety is primary ($-\text{NH}_2$), but some (e.g., sarcosine) are secondary ($-\text{NH}-$) amines, and others containing tertiary amines (e.g., proline) are referred to as imino ($=\text{N}-$) acids. Amino acids that occur in protein are referred to as α -amino acids (Fig. 18.1) because the amine moiety is linked to the α -carbon atom. The α carbon atom is directly adjacent to the carboxyl group, while carbon atoms successively distal to the carboxyl are referred to as the β - and γ -carbon, respectively. Not all biologic amino acids are α -amino acids. β -amino acids (β -alanine and taurine) as well as γ -amino acids (γ -aminobutyric acid, GABA) also play key biochemical roles. Some of these atypical amino acids are shown in Fig. 18.2.

With the exception of glycine, all α amino acids contain four distinct moieties asymmetrically arranged around the central " α " carbon. As a consequence, amino acids exist as mirror images (enantiomers) referred to as the *D* or *L* configuration. With few exceptions, the biologically relevant amino acids exist in the *L*

TABLE 18.1 Structure and Chemical Properties of the 20 Proteogenic Amino Acids

Amino Acid	MW (Da)	Structure (pH 7.0)	pK ₁	pK ₂	pK ₃	pI	HI
Alanine (ALA, A)	89.09		2.4	9.7		6.0	1.8
Arginine (ARG, R)	174.20		2.2	9.0	12.5	10.8	-4.5
Asparagine (ASN, N)	132.12		2.0	8.8		5.4	-3.5
Aspartate (ASP, D)	133.10		2.1	9.8	3.9	2.9	-3.5
Cysteine (CYS, C)	121.16		1.7	10.8	8.3	5.1	2.5
Glycine (GLY, G)	75.07		2.3	9.6		6.0	-0.4
Glutamate (GLU, E)	147.13		2.2	9.7	4.3	3.2	-3.5
Glutamine (GLN, Q)	146.15		2.2	9.1		5.7	-3.5
Histidine (HIS, H)	155.16		1.8	9.2	6.0	7.6	-3.2
Isoleucine (ILE, I)	131.17		2.4	9.7		6.0	4.5
Leucine (LEU, L)	131.17		2.4	9.6		6.0	3.8
Lysine (LYS, K)	146.19		2.2	9.0	10.5	9.7	-3.9
Methionine (MET, M)	149.21		2.3	9.2		5.8	1.9

TABLE 18.1 Structure and Chemical Properties of the 20 Proteogenic Amino Acids—cont'd

Amino Acid	MW (Da)	Structure (pH 7.0)	pK ₁	pK ₂	pK ₃	pI	HI
Phenylalanine (PHE, F)	165.19		1.8	9.1		5.5	2.8
Proline (PRO, P)	115.13		2.1	10.6		6.1	1.6
Serine (SER, S)	105.09		2.2	9.2		5.7	-0.8
Threonine (THR, T)	119.12		2.6	10.4		6.5	-0.7
Tryptophan (TRP, W)	201.22		2.5	9.4		5.9	-0.9
Tyrosine (TYR, Y)	181.19		2.2	9.2	10.5	5.7	-1.3
Valine (VAL, V)	117.17		2.3	9.6		6.0	4.2

Three-letter and single-letter definitions of the amino acids are included in parentheses.

HI, Hydropathy index; MW, molecular weight; *p*k, acid ionization constant; *p*I, isoelectric point.

Fig. 18.1 Planar representation of an α -amino acid. “R” represents unique side chain specific to each amino acid.

configuration. Small quantities of *D* amino acids occur in physiological fluids but typically do not have specific functions. An exception is *D* serine, which represents 5% to 20% of total serine in cerebrospinal fluid and may serve as a neurotransmitter. Amino acids with the *D* configuration occur in some bacterial products, foods, and pharmaceuticals but are metabolized in the liver and kidney. Two amino acids, threonine and isoleucine, have a second asymmetric carbon that gives rise to stereoisomers referred to as *allothreonine* and *alloisoleucine*. The latter compound has utility in the diagnosis of maple syrup urine disease.

In addition to the 20 protein-forming amino acids, a number of rare amino acids are recovered from protein hydrolysates. For example, 4-hydroxyproline and 5-hydroxylysine are found in collagen. Desmosine and isodesmosine are recovered from elastin. These amino acids are formed by posttranslational

mechanisms because no codon is responsible for their incorporation into growing polypeptides. Selenocysteine is a rare amino acid incorporated into just a few protein sequences (e.g., iodothyronine deiodinase). The structures of some of these rare amino acids are included in Fig. 18.2.

Acid-base properties of amino acids depend on the amino and carboxyl groups attached to the α carbon and on basic or acidic groups that may occur on side chains (R). At pH 7.4, the α -carboxyl group is ionized and carries a negative charge, while the α amino group is protonated and carries a positive charge. Molecules existing simultaneously as cations and anions are referred to as zwitterions (Fig. 18.3).

The pH at which ionizable groups exist equally as charged and uncharged forms is known as the *p*K. Amino acids thus have two or more *p*Ks—one for the carboxyl, one for the amino group, and an additional one in the presence of an ionizable side chain. The isoelectric point (*p*I) is the pH at which an amino acid or other molecule has a net charge of 0. For a typical neutral amino acid such as glycine, the *p*I of 5.97 is midway between the *p*K of 2.34 for the carboxylic acid and the *p*K of 9.60 for the amino group. The *p*Ks of amino acid side chains in proteins vary somewhat from those in free amino acids because of the influence of neighboring amino

Fig. 18.2 Planar structures of rare or unusual, naturally occurring amino acids.

Fig. 18.3 Planar schematic of an α-amino acid as a zwitterion.

acids. The buffering capacity of ionizable groups is primarily in a pH range within ± 1 unit of the pK for the respective groups. Amino acids and proteins therefore have a limited buffering capacity near physiologic pH. The imidazole side chain of histidine is an exception, with a pK near 6.0.

The structural diversity of side chains permits formation of proteins with a variety of structure and function. Side chain diversity is dictated not only by pK but by size and hydrophobicity as well. Amino acids with longer aliphatic or aromatic side chains such as isoleucine, leucine, and phenylalanine have greater hydrophobicity than shorter side chains, such as the methyl group found in alanine. Neutral amino acids with polar groups such as hydroxyl or amide groups in their side chains are more hydrophilic. Acidic amino acids have side chains with carboxylic acids, and basic amino acids have side chains with amino, guanidino, or imidazole groups. The thiol side chain ($-\text{SH}$) of cysteine oxidizes easily and may become linked to other molecules via a disulfide bond. In plasma, cysteine occurs as cystine (cysteine homodimer linked via a disulfide) or as a mixed disulfide with albumin or other proteins.

With some exceptions, amino acids are water soluble and stable in plasma. The most soluble amino acids have small side chains with polar or ionizable moieties such as glycine, alanine, arginine, serine, and threonine. Less soluble amino acids such as phenylalanine, tyrosine, leucine, and tryptophan tend to have larger, nonpolar aliphatic or alicyclic side chains. Amino acid solubility is rarely limiting in vivo, except in some metabolic disorders. Deposition of tyrosine crystals in the eye and skin is common in tyrosinemia. Likewise,

cystine may crystallize in the renal parenchyma in patients with cystinuria.

Amino Acid Supply and Transport

In addition to serving as substrates for protein synthesis, amino acids participate in many metabolic pathways. In the healthy state, women require approximately 46 g/day and men approximately 56 g/day of dietary protein (0.8 g/kg body weight), and substantial increases in demand occur during growth and in many disease states. Dietary protein is digested by proteases in the stomach (e.g., pepsin) and small intestine (e.g., trypsin, chymotrypsin) to yield amino acids. Endogenous protein turnover serves as another source of free amino acids. Eight amino acids used for protein synthesis (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine) are not synthesized by humans and therefore are considered “essential” constituents of the diet. Meat, milk, eggs, and fish contain a full range of **essential amino acids**. Gelatin is deficient in tryptophan, and some plant sources of protein may be additionally deficient in lysine or methionine. Therefore diets based on a single source of plant protein may be deficient in some amino acids. When liver function is compromised, cysteine and tyrosine become essential because they are not converted from their usual precursors, methionine and phenylalanine. Arginine may be conditionally essential as well, because endogenous rates of synthesis may be insufficient to meet requirements in adults under metabolic stress or in growing children.

Requirements for dietary protein to maintain nitrogen balance increase in infancy and childhood when there are increased demands for growth. Daily requirements increase by up to 3.5 to 4 g protein/kg body weight for premature infants, for example. Protein demand is also increased in pregnancy, lactation, and states of protein loss or catabolic states (e.g., burn patients). Persistent negative nitrogen balance results in a number of undesirable phenotypic features.

Fig. 18.4 A generalized scheme of amino acid metabolism in the liver. After transamination, amino acid carbon may be used in the Krebs cycle or transformed into respiratory fuels such as glucose and ketones. Waste nitrogen is disposed of via the urea cycle. *ATP*, Adenosine triphosphate; *CoA*, coenzyme A.

A diet severely deficient in protein and consisting primarily of high-starch foods can lead to **kwashiorkor**, a disorder characterized by decreased serum albumin, immune deficiency, edema, ascites, growth failure, apathy, and many other symptoms. **Marasmus** results when protein and energy sources such as carbohydrates are deficient, causing wasting of muscles and subcutaneous tissues. Albumin or prealbumin concentrations can be used to assess adequacy of the amino acid supply. The shorter biologic half-life of prealbumin compared with albumin (2 vs. 20 days) makes it a valuable marker for acute dietary assessment.

Homeostasis of cellular amino acid concentrations is dependent on supply, catabolism, and excretion. Supply and excretion are regulated by a series of transport systems with overlapping substrate specificity, strategic tissue expression, and polarized cellular distribution. Amino acids are derived from dietary protein precursors through the action of proteolytic enzymes in the stomach and small intestine that produce shorter oligopeptides and individual amino acids. Enteral absorption of di- and tripeptides is mediated by a single proton-coupled transport system termed PEPT1 (encoded by *SLC15A1*). Transport of individual amino acids across the intestinal and renal epithelium as well as the blood–brain barrier is far more specialized.

A diverse array of transport systems consisting of multiple polypeptide chains has evolved for both inter- and intracellular amino acid transport. Some transporters require energy, while others rely on established concentration gradients. The substrate specificity of these systems is often broad. For example, distinct systems are responsible for transporting

branched-chain, cationic, anionic, or hydrophobic amino acids. Multiple different systems often cooperate to achieve amino acid absorption across the gut or renal epithelia. Defects in these transport systems are responsible for a number of disease states including cystinuria, cystinosis, lysinuric protein intolerance, or HHH (hyperornithinemia, hyperammonemia, homocitrullinuria) syndrome.

Amino Acid Metabolism

Amino acids serve as scaffolds for the synthesis of many hormones, nucleotides, lipids, signaling molecules, and metabolic intermediates that play a role in energy production. As portrayed in Fig. 18.4, the transformation of amino acid carbon to energetic intermediate typically begins with transamination. Excess nitrogen is ultimately excreted as urea. Resulting α -ketoacids may enter the Krebs cycle; undergo conversion to ketone bodies, fatty acids, or glucose; or be completely oxidized to CO_2 , depending on cellular energy demands. A vast array of enzyme networks has evolved to orchestrate demand for amino acids.

Glucose, fatty acids, and ketones are primary respiratory substrates in humans. These substrates generate adenosine triphosphate (ATP) via the mitochondrial Krebs cycle. Amino acids play two key roles in energy provision. First, amino acids are converted to Krebs cycle intermediates to maintain the activity of the cycle in a process called anaplerosis. Glutamine and glutamate, for example, are converted to α -ketoglutarate. Fumarate may be derived from asparagine and aspartate, and succinate is derived from methionine, threonine, and valine. Second, amino acids may be mobilized

to generate fuels for a variety of organ systems. Five amino acids (LEU, ILE, LYS, PHE, and TYR) may be converted to ketones. All of the amino acids except for leucine may be used to produce glucose. In times of high energy demand and limiting fuel sources, therefore, flux of amino acid carbon through proper pathways becomes an important source of respiratory fuel.

Excess tissue nitrogen is disposed of as urea, which contains two moles of nitrogen per mole. Urea production is limited to the liver, so selected amino acids, primarily glutamine and alanine, serve to shuttle excess nitrogen to the liver. Nitrogen in the form of ammonium ion is first converted to carbamoyl phosphate, which is transferred to ornithine to form citrulline. Aspartate and citrulline are condensed to form argininosuccinate, which, in turn, is cleaved to arginine and fumarate. Arginase hydrolyzes arginine to urea and ornithine to allow the cycle to repeat. Urea is usually viewed simply as waste, but it is also the primary contributor to the high osmolality in the renal medulla and enables maximal urinary concentrating ability.

Amino acids are precursors for many hormones and signaling molecules. Tyrosine provides a scaffold for thyroxine, dopamine, and adrenaline synthesis. Tryptophan is a precursor of serotonin and melatonin. The potent vasodilator nitric oxide (NO) is produced from arginine. Glycine, aspartate, glutamine, and serine contribute atoms to purine and pyrimidine synthesis. Glycine and arginine are precursors for creatine synthesis.

Creatine synthesis and many other biochemical processes rely on a series of single-carbon transfer reactions mediated by serine, glycine, histidine, and methionine. Transfer of fully oxidized carbonyl carbon ($=C=O$) to molecules such as propionyl coenzyme A (CoA) (to form methylmalonyl CoA) is mediated by biotin. Glycine, serine, and histidine contribute less oxidized carbon units such as methylidyne ($=CH-$), and methylene ($-CH_2-$) groups that enable purine and pyrimidine synthesis via folate derivatives. Folate also mediates transfer of methyl ($-CH_3$) groups to homocysteine to form methionine. The resulting methionine is, in turn, activated to S-adenosylmethionine, becoming a methyl donor to a vast array of substrates including DNA, RNA, histones, choline, and catecholamines. The importance of folate and single-carbon metabolism to cell growth and division cannot be overstated. Folate deficiency in a developing embryo can lead to death or severe neurologic birth defects. The use of folate antimetabolites such as methotrexate has been a mainstay in the treatment of cancer for many decades.

Amino Acid Concentrations

Plasma amino acid concentrations collectively span a 1000-fold dynamic range from very low micromolar quantities (e.g., β -alanine, cystathionine) to near 1 mmol/L (e.g., glutamine, glycine). With protein intake of 1 to 2 g/kg, daily variation of amino acid concentrations approaches 30% in healthy adults. Concentrations of both essential and nonessential amino acids vary in a coordinated way, suggesting that

mechanisms beyond diet and enteral extraction are responsible. Amino acid concentrations tend to peak between 12 and 8 p.m., with a nadir between midnight and 4 a.m. After an ingested protein bolus, dietary amino acids rise and tend to return to preprandial levels in 3 to 6 hours. Determination of “fasting” amino acid concentrations, therefore, requires extended periods of dietary abstinence.

Most amino acids in blood undergo glomerular filtration but are efficiently reabsorbed in proximal renal tubules by previously described saturable transport systems. Increased renal excretion of amino acids (**aminoaciduria**) results from the filtration of excessive plasma concentrations, generalized tubular impairment, or heritable defects in amino acid transport systems. Glycine tends to be most abundant in normal urine, followed by histidine, glutamine, and serine. Increased concentrations of proteogenic amino acids in plasma tend to precipitate only mildly elevated excretion because of efficient reabsorption. Other amino acids that accumulate in plasma secondary to metabolic errors (e.g., argininosuccinate, homocitrulline) demonstrate pronounced excretion because of the absence of specific tubular mechanisms enabling reclamation from the filtrate.

With the exception of glutamine, cerebral spinal fluid (CSF) amino acid concentrations are typically less than 10% of those found in plasma. This high plasma to CSF gradient suggests active net brain to blood transport across the blood-brain barrier. Glutamine concentrations in CSF are generally equal to those in plasma, suggesting a bidirectional facilitative transport process. Insofar as CSF concentrations reflect synaptic concentrations, the regulation of neurotransmitter amino acid concentrations is critical for normal neural action potential propagation. Glutamate is the most abundant amino acid in the brain and is the primary excitatory transmitter. Glycine and GABA are the predominant inhibitory transmitters. Lumbar puncture to access the CSF amino acid pool must be done with great care to avoid overestimation of central amino acid concentrations secondary to contamination with peripheral blood.

Analysis of Amino Acids

For decades, the standard method of amino acid analysis was cation-exchange chromatography with postcolumn spectrophotometric or fluorescent detection of amine derivatives. Derivatizing agents have included dansyl chloride, o-phthalaldehyde, and ninhydrin. The ninhydrin approach developed in the 1950s was initially applied to determination of amino acid content of protein hydrolysates and then adapted for profiling of free amino acids in deproteinized body fluids. Other systems commercialized by Beckman (Brea, CA) and Hitachi (Tokyo, Japan) were large floor models and required as long as 2 to 3 hours to quantitate 30 to 50 physiologic amino acids in a single patient specimen. These systems have given way to smaller bench-top systems using ninhydrin (Biochrom, Cambridge, United Kingdom) or fluorescent (quinolyl-N-hydroxysuccinimidyl) amine derivatives (Waters, Milford, MA) that still require 90 to 120 minutes for full sample analysis. In addition to long

cycle times, these methods are subject to interference from co-eluting amines, leading to overestimation of some amino acid concentrations.

Mass spectrometry (MS) is gaining favor as the method of choice for amino acid profiling. Newborn screening programs quantitate amino acid butyl esters derived from dried blood spots using flow-injection MS protocols. These methods do not use chromatographic separation and so cannot distinguish between isomeric or isobaric amino acids such as leucine, isoleucine, alloisoleucine, and hydroxyproline. Liquid chromatography–tandem mass spectrometry (LC-MS/MS) methods capable of distinguishing some isomers and isobars in plasma and other body fluids have also been developed. Some of these use amine-targeted derivatives, others target the carboxyl group, and some others employ no chemical derivatization. Advantages of MS techniques include improved analytic specificity, a 3- to 4-order-of-magnitude dynamic range, and rapid (20-minute) throughput. MS methods may also be optimized for profiling multiple molecular species in addition to amino acids. Such approaches promise to improve the scope of metabolic disorders detectable with a single patient specimen in a single analytic run.

PEPTIDES

This section describes the basic biochemistry of peptides. In general, the term *peptide* applies to relatively short polymers of amino acids with molecular weights less than 6000 Da (<~50 amino acid residues). The chemistry of the peptide bond and the physical characteristics of the peptide backbone are discussed in this section, along with a number of clinically relevant peptide systems.

Peptide Bond

A **peptide bond**, also referred to as an amide bond, is formed between the α -nitrogen atom of one amino acid and the carbonyl carbon of a second (Fig. 18.5). So-called isopeptide bonds refer to amide bonds between side chain amines or carbonyl carbons, rather than α -amine or α -carbonyl. In glutathione, for example, the γ -carboxyl group of glutamic acid is linked to the α -amino group of cysteine. During translation, peptide bonds are formed from the amino (N) to the carboxyl (C) terminus by removal of water (also referred to as dehydration or condensation) and catalyzed by RNA (referred to as a ribozyme) that forms part of the ribosome. Peptides are also synthesized *in vitro* for therapeutic and experimental purposes. Cleavage of peptide bonds may be nonspecifically achieved by acid hydrolysis or accomplished specifically by a

host of proteolytic enzymes with affinity for bonds between specific amino acid residues. These protease systems are described later in this chapter.

Peptide Heterogeneity and Analysis

The assessment of circulating peptide concentrations has a number of limitations. In the absence of enzymatic activity, peptide measurements have been historically limited to immunologic techniques. Antibodies may recognize linear sequence epitopes or discontinuous, conformational epitopes. These epitopes typically involve 10 to 20 amino acids binding exposed areas of 600 to 1000 Å. Measurements of short peptides (<20 to 30 amino acids) are therefore limited to single-site, competitive assays that lack the analytic specificity of two-site (sandwich) immunoassays. The molecular specificity issues may be addressed using MS as an alternative. Small peptides may be ionized via electrospray (ESI) or matrix-assisted laser desorption (MALDI) and interfaced to tandem quadrupole mass analyzers. Refer to Chapter 13 for additional information on mass spectrometers.

Absolute analytic specificity is not always ideal when applied to biologic peptide systems. Peptide populations may consist of species with a variable number of amino acid residues with sometimes unknown biologic potency. Hepcidin, for example, is an iron transport regulatory peptide that circulates principally as a 25-amino acid peptide but also as shorter peptides of 22 and 20 amino acids with diminished biologic activity. Likewise, dozens of truncated forms of the mature 32-amino acid B-type natriuretic peptide (BNP), ranging from 24 to 31 amino acids, are detectable in heart failure patients. Some of these truncated forms are present *in vivo*, and others likely develop *in vitro* following sample acquisition. Thus narrowly targeted MS assays may exclude active peptide species and run the risk of underestimating bioactive peptide. Cross-reactive immunoassays, on the other hand, may stoichiometrically detect both active and inactive peptide, thus running the risk of overestimating bioactive peptide concentrations. Examples of several important biologic peptide systems and their analytic considerations follow.

Clinically Relevant Peptide Systems

Pro-Opiomelanocortin System

The pro-opiomelanocortin (POMC) gene on chromosome 2 is expressed primarily in the pituitary gland, arcuate nucleus of the hypothalamus, and skin melanocytes. The gene produces a 241-amino acid prohormone that can yield as many as 10 distinct biologically active peptides, depending on patterns of cleavage in specific tissue types. The POMC peptides have diverse effects on glucose and electrolyte homeostasis (via adrenocorticotrophic hormone [ACTH]), body mass and appetite (via lipotropins and melanocortins), pigmentation (also via melanocortins), and pain (via endorphins). Clinical exploitation of this complex peptide system is currently limited to the impact of ACTH on the adrenal gland and subsequent feedback by cortisol. Measurement of circulating ACTH concentrations is used to clarify the mechanism of

Fig. 18.5 Formation of peptide bond between α -amino and α -carbonyl of adjacent amino acids.

adrenal disease. For example, Cushing disease may result from autonomous adrenal function or may be fueled by ectopic ACTH production. Likewise, Addison disease may result from adrenal or pituitary failure.

Natriuretic Peptides

This peptide family consists of atrial natriuretic peptide (ANP), BNP (formerly brain natriuretic peptide), and C-type natriuretic peptide (CNP). ANP and BNP are highly expressed in cardiac tissue relative to CNP, which is expressed at low levels in a broad variety of tissue types. The mature forms of these peptides contain a 17-amino acid loop stabilized by an intramolecular disulfide bond. Each peptide acts via a specific guanylate cyclase-coupled receptor to promote sodium and water excretion, blunt activation of the renin-angiotensin system, and decrease vascular resistance. Circulating concentrations of ANP and BNP (but not CNP) increase rapidly in response to increased cardiac filling pressures that are characteristic of heart failure. Clinical measurement of BNP has become a widely used tool to detect heart failure and monitor its progression. For additional information on the clinical utility of these peptides, refer to [Chapter 34](#).

B-type natriuretic peptide is synthesized as a 108-amino acid precursor (pro-BNP) that is cleaved upon cellular release to the active 32-amino acid peptide and an N-terminal fragment (NT-proBNP), which lacks biologic activity. Two-site immunoassays for both BNP and NT-proBNP are commercially available and widely used. NT-proBNP circulates at a higher concentration than BNP by virtue of its longer biologic half-life (~60 minutes vs. ~20 minutes). Recent evidence suggests that the BNP detected immunologically in heart failure is not the bioactive form of BNP. These studies suggest that the immunoreactive BNP in the plasma of heart failure patients may be attributed to higher molecular weight forms such as proBNP that exhibit a fraction of the bioactivity of the mature peptide. This new analytic information may prompt a reevaluation of the role of BNP in the pathophysiology, diagnosis, and treatment of heart failure.

Hepcidin

Hepcidin was initially described as an antimicrobial peptide. The role of hepcidin in iron metabolism was noted by Nicolas et al. in 2001. The mature 25-amino acid molecule is derived from a 60-amino acid precursor expressed from three exons of the *HAMP* gene on chromosome 19. The tightly looped structure of hepcidin is stabilized by four intramolecular disulfide bonds. The biologic activity of hepcidin is mediated via its interaction with ferroportin, the transport protein that mediates iron transport from duodenal enterocytes and macrophages. Hepcidin binding promotes the internalization and degradation of ferroportin, thus inhibiting mobilization of iron stores. Physiologic states such as chronic inflammation are characterized by microcytic anemia with paradoxically adequate iron stores known as anemia of chronic disease. Increased hepcidin expression is at the pathologic root of this condition.

Despite the important role of hepcidin in iron metabolism, its clinical use remains infrequent partly because of difficulties associated with its measurement. Antibodies toward hepcidin have been difficult to develop because of its small, compact size, and because it is highly conserved across multiple species. Immunoassays have largely been limited to single-site, competitive formats that cross-react significantly with shorter versions of the molecule (22-, 20-mers). This can lead to overestimation of circulating hepcidin compared with MS techniques. Improvements in the molecular specificity and harmonization of hepcidin determination promise to enhance its clinical utility. For additional information on the clinical utility and measurement of hepcidin, refer to [Chapter 28](#).

Angiotensins

Renin is secreted by the afferent arterioles of the kidney in response to decreased flow, pressure, and sodium delivery to the renal juxtaglomerular apparatus. Renin acts on circulating angiotensinogen to initiate the formation of vasoactive peptides that act to reestablish glomerular flow. The decapeptide known as angiotensin I is cleaved from the 452-amino acid angiotensinogen molecule. Angiotensin-converting enzyme (ACE) cleaves two C-terminal residues from angiotensin I to form the octapeptide, angiotensin II, which promotes contraction of vascular smooth muscle and stimulates proximal tubular sodium reabsorption to increase blood pressure. ACE inhibitors (e.g., captopril, enalapril, quinapril) are important pharmacologic tools used to treat hypertension. For additional information, refer to [Chapters 34 and 35](#).

Although the renin-angiotensin-aldosterone axis is an important therapeutic target, it is an infrequent target for diagnostic laboratory studies. Plasma renin activity is assessed to explore the possibility of renovascular hypertension. In this condition, unilateral restriction of renal blood flow results in the inappropriate release of renin and severe hypertension. Renin activity in the plasma is normally very low (<10 ng/mL per hour) and is typically measured by assessing the production of angiotensin I from endogenous angiotensinogen after a long incubation period (>12 hours). Angiotensin I generation is most commonly monitored via a competitive immunoassay with the potential to cross-react with shorter peptides. MS approaches that address peptide specificity and stability may mitigate these analytic limitations.

Endothelins

Endothelins (ETs) are peptides with 21 amino acids derived from the vascular endothelium (ET-1), intestinal and renal tissue (ET-2), and neural tissue (ET-3). ET-1 is produced from a 203-amino acid precursor (preproendothelin) and smaller, 30- to 40-amino acid “big” ET molecules that are inactive. ET-1 is a potent vasoconstrictor and may mediate pathology associated with diabetic nephropathy and hypertension. The current clinical utility of ET measurement is limited.

Vasopressin

Vasopressin (arginine vasopressin [AVP]), also known as antidiuretic hormone (ADH), is a nonapeptide stored in and secreted from the posterior pituitary gland. For additional information, refer to [Chapter 40](#). Its primary target organ is the distal convoluted tubule and collecting duct, where it acts to promote water reabsorption. ADH circulates at very low concentrations (<40 pmol/L) and has a very short half-life (15 to 20 minutes), making routine diagnostic measurement impractical. Diabetes insipidus (DI) may result from faulty secretion (central DI) or from end-organ resistance (nephrogenic DI). Head injury, tumors, and some medications may also induce pathologic secretion of ADH, resulting in fluid overload, referred to as the syndrome of inappropriate antidiuretic hormone secretion (SIADH). A synthetic analog referred to as DDAVP (1-desamino, 8-D-AVP) is used therapeutically to treat DI and some forms of coagulopathy. DDAVP stimulates release of von Willebrand factor from endothelial cells and extends the half-life of circulating factor VIII, thereby mediating improvements of circulating hemostatic factors associated with various forms of von Willebrand disease and hemophilia A.

Glutathione

Glutathione consists of a glutamate residue linked to cysteine via its γ -carboxyl rather than the α -carboxyl group, followed by a conventional peptide bond between cysteine and glycine. This ubiquitous tripeptide is the most abundant intracellular thiol and circulates in the blood at micromolar concentrations. The cellular ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG) ranges from 10 to 100. Intracellular glutathione performs a variety of important functions. It plays a role in maintaining the proper ratio of oxidized to reduced forms of metabolically important thiols such as coenzyme A. It also provides reducing equivalents that detoxify reactive oxygen species such as peroxides. Through the activity of glutathione-S-transferase, glutathione also serves to detoxify other xenobiotic compounds via formation of a thioether derivative, which is then excreted. Amines and peptides are transported across the plasma membrane via the γ -glutamyl moiety of glutathione, a reaction catalyzed by γ -glutamyl-transpeptidase. Determination of circulating GSH and GSSG is not routinely called for in clinical practice, as the site of action is intracellular. Inborn errors of glutathione metabolism such as glutathione synthetase deficiency are detected via the accumulation of components of the γ -glutamyl cycle, such as pyroglutamic acid (5-oxoproline).

PROTEINS

The structural diversity of proteins may be described using the following features:

1. Primary structure is the linear sequence of amino acids in a peptide or protein. Posttranslational modifications of amino acids contribute to increased diversity.
2. Secondary structure describes the nature of the peptide backbone dictated by peptide bond angles described

earlier and stabilized by hydrogen bonds. Examples of secondary structure include α -helix, β -sheet. Random coils refer to segments of peptide that lack defined secondary structure.

3. Tertiary structure refers to the folding of the polypeptide chain and elements of secondary structure into a compact three-dimensional (3D) shape. Folding is a complex process driven by intramolecular and solvent interactions. Hydrophobic groups tend to fold into the interior with less exposure to solvent, while charged and polar side chains tend to be located on the surface. 3D structure is stabilized by hydrogen bonds, hydrophobic interactions, and covalent disulfide bonds. Loss of tertiary structure (denaturation) is induced by temperature, organic solvents, and detergents. Limited denaturation can be reversible, but extensive unfolding and denaturation of proteins often lead to irreversible aggregation.
4. Quaternary structure refers to the incorporation of two or more polypeptide chains or subunits into a larger multimeric unit. Examples range from the relatively simple creatine kinase, a heterodimer of M and B subunits, to branched chain α -ketoacid dehydrogenase, which is a heteromeric complex of 42 (12 E1, 24 E2, and 6 E3) subunits.
5. Ligands and prosthetic groups provide additional functional and structural elements. Examples include metals in metalloenzymes, heme in hemoglobin and cytochromes, and lipids in lipoproteins. Proteins without their associated ligands are often referred to as apoproteins (e.g., apotransferrin without iron, apolipoproteins without lipid).

Physical Properties of Proteins

Differing physical properties serve as the basis of methods to separate proteins. Some important characteristics include the following:

1. *Differential solubility.* The solubility of proteins is affected by pH, ionic strength, temperature, and the characteristics of the solvent. Changing solvent pH affects the net charge of a protein. Changing ionic strength affects the hydration and solubility of proteins. The addition of organic solvents and polyethylene glycol is also useful for differential precipitation.
2. *Molecular size.* Separation of small and large molecules is commonly achieved by filtration, ultracentrifugation, and electrophoresis. These techniques may be used under conditions when proteins and peptides are in native globular states or under denaturing conditions. The addition of reducing agents allows separation of disulfide-linked components.
3. *Molecular mass.* Advances in MS allow the determination of masses of peptides and proteins with increasing accuracy.
4. *Electrical charge.* Ion-exchange chromatography, **isoelectric focusing**, and electrophoresis separate peptides and proteins based on charge.
5. *Surface adsorption.* The affinity of peptides and proteins for a variety of physical surfaces may also be used as the basis for separation. Reverse-phase chromatography, for

example, exploits the interaction of hydrophobic molecular moieties with hydrophobic surfaces (C8 or C18 alkyl chains) when the ratio of water to organic solvent is high, but not when organic content is increased.

6. *Affinity chromatography.* Specific ligands, antibodies, and other recognition molecules have been used to separate peptides or proteins selectively.

Protein Formation

Folding

Proteins are synthesized by ribosomes starting from the 5'-end of mRNA. Triplet codons in mRNA are matched with complementary sequence in transfer RNA carrying specific amino acids. Protein synthesis begins with an AUG codon encoding methionine, and the polypeptide chain is synthesized from the N-terminus.

Instructions for folding are largely contained in the primary amino acid sequence of the growing polypeptide chain. The rate of elongation may have a significant impact on folding. Pauses in translation enhance formation of secondary structural elements. Folding begins as the chain is elongated and assisted by a family of proteins referred to as chaperones. Protein folding is an error-prone process, and many molecular chaperones work to refold, prevent aggregation, or degrade misfolded proteins.

Despite such protective mechanisms, several age-related, genetic, and infectious diseases appear connected to abnormal protein folding and aggregation. Prion diseases are infectious diseases in which the transmissible protein agent may catalyze misfolding of endogenous proteins. In Alzheimer disease, deposits of amyloid may contribute to pathogenesis. Polyglutamine diseases result from genetic expansion of repeat units encoding glutamine and are associated with Huntington disease and other neurodegenerative disorders. Amyotrophic lateral sclerosis (Lou Gehrig disease) results from aggregation of transactive DNA-binding proteins. Several inherited disorders also result from mutated, misfolded proteins. In α_1 -antitrypsin (AAT) deficiency, liver injury results from aggregation and accumulation of misfolded protein. Cystic fibrosis is most commonly caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) that result in rapid degradation of incompletely folded protein. Small molecule therapeutics capable of modulating protein folding have shown some promise in mitigating disease caused by abnormal protein aggregation.

Targeting

Proteins that are secreted or located in vesicles and membranes usually contain a hydrophobic N-terminal signal peptide about 15 to 30 amino acids in length. These signal peptides mediate interaction with the endoplasmic reticulum (ER) and are typically removed even before synthesis of the entire protein chain is completed. Membrane retention may be achieved via an uncleaved signal sequence, by one or more hydrophobic transmembrane domains, or by lipid modifications such as N-myristoylation. Newly synthesized proteins ultimately reside in a number of membranous or soluble compartments,

including the nucleus, lysosome, peroxisome, mitochondrion, or plasma membrane. Plasma membrane sorting is further complicated in polarized epithelial cells where proteins may be targeted to basolateral or apical environments.

Posttranslational Modifications

Fatty Acylation

The activity and location of proteins may be modulated by the covalent attachment of fatty acyl chains. Attachment of myristate via a glycine residue promotes membrane association. Palmitoylation of cysteine residues controls localization to membrane microdomains known as lipid rafts and caveolae. Examples of palmitoylated proteins include caveolin-1 and some members of the SRC protein kinase family. Ghrelin, a potent growth hormone secretagogue, is modified by covalent attachment of an octanoyl moiety. Only octanoylated ghrelin promotes growth hormone release.

Phosphorylation

Reversible phosphorylation may impact as many as one-third of all human cellular proteins. The human genome encodes approximately 1000 kinases responsible for phosphorylation, and about 500 phosphatases responsible for removal of covalent phosphate groups. O-phosphorylation occurs at serine, threonine, and tyrosine residues. In general, serine and threonine phosphorylation acutely modifies enzyme activity and subcellular localization. Tyrosine phosphorylation, on the other hand, regulates a plethora of signaling pathways.

Prenylation

Isoprenoids are hydrophobic moieties formed as byproducts of the cholesterol synthetic pathway. These groups modify more than 300 members of the human proteome. Isoprenylation regulates membrane and molecular association of a number of proteins important for signal transduction, vesicular trafficking, cytoskeletal function, and the integrity of the nuclear membrane.

Glycosylphosphatidylinositol Anchor

The glycosylphosphatidylinositol (GPI) anchor is a glyco-glycerophospholipid construct that mediates membrane attachment for a variety of proteins. GPI-modified proteins associate with the membrane via interdigitation of two fatty acyl chains with a single membrane leaflet. The purpose of the GPI anchor remains unclear, although lipid-anchored proteins may diffuse more rapidly in the lateral plane of membranes than transmembrane proteins. Defects in GPI synthesis are responsible for paroxysmal nocturnal hemoglobinuria.

γ -Carboxylation

Glutamic acid is a five-carbon α -amino dicarboxylic acid. Vitamin K enables the addition of a second carboxyl group to the γ -carbon of glutamate. A cluster of γ -carboxylated glutamyl residues is referred to as a "gla" domain. This modification mediates calcium-dependent membrane association and is required for full functional activity. Many proteins of the coagulation cascade contain the gla domain, including thrombin, factors VII, IX, and X, and protein C, S, and

Z. Warfarin exerts its anticoagulant effect by abrogating the activities of these vitamin K-dependent factors.

Glycosylation

Secreted proteins and the extracellular domains of membrane proteins are commonly modified with carbohydrate. Carbohydrate plays an important role in folding, secretion, and stability of the modified polypeptide. Sugar chains are added in the ER and Golgi apparatus via O-linkage to serine and threonine residues or N-linkage to the amide nitrogen of asparagine residues. O-linked sugar modifications are typically simple and consist of one to four residues. N-linked sugars are far more complex. Approximately 200 human gene products are involved in glycosylation, and more than 100 genetic defects in this process have now been documented.

Sulfation

Sulfation of proteins may occur on tyrosine residues. Nearly 50 secreted and membrane proteins carry this irreversible modification that occurs in the Golgi apparatus. Examples of sulfated proteins include coagulation factors V, VIII, and IX, fibrinogen, thyroglobulin, and α -fetoprotein. Sulfation may modify molecular recognition events. A naturally occurring TYR $\rightarrow$ PHE at position 1680 of factor VIII, for example, prevents sulfation and weakens its interaction with von Willebrand factor, causing a mild form of hemophilia.

Hydroxylation

Hydroxylation is the most prevalent posttranslational modification of human proteins. Hydroxylation most commonly occurs at the 4 position of the proline ring in collagen molecules. Hydroxylation of proline residues is thought to alter polypeptide flexibility, which stabilizes the structure of collagen and other connective tissue proteins (e.g., elastin).

Nitrosylation

NO is a volatile free radical produced from arginine via three human nitric oxide synthase (NOS) enzyme systems. NO exerts its primary biologic effects (e.g., vasodilation) via guanylate cyclase-coupled receptors, but it also forms covalent nitrosothiol (S–N=O) derivatives with protein cysteine residues. Thousands of proteins with a diverse array of functions are reversibly modified in this way. The role of protein nitrosylation in health and disease remains to be fully clarified.

PROTEIN CATABOLISM

The steady-state concentration of any protein reflects its rate of synthesis and its rate of degradation. The degradative process is more than a passive, nonspecific mechanism for disposing of unwanted cellular material. It is highly specific and tightly controlled. As supporting evidence, consider that the human genome contains more than 500 proteases. These proteases belong to one of four families based on the catalytic mechanism for hydrolyzing peptide bonds. Representative members of the four protease families are detailed in [Table 18.2](#).

Protease Families

Serine Proteases

The serine proteases are the most abundant family in humans and are so named because serine serves as the nucleophilic residue at the active site of the enzyme. Serine protease inhibitors (serpins), including AAT, antithrombin, and protein C, inactivate a broad variety of serine proteases. Some members of the serpin family, including angiotensinogen and thyroxine-binding globulin, do not possess known activity against specific proteases.

Cysteinyll Proteases

This group of proteases uses a cysteine thiol in nucleophilic attack on the peptide bond. In humans, cysteine proteases mediate apoptosis via a series of enzymes referred to as caspases. Other notable cysteine proteases include members of the cathepsin family and interleukin-1 β -converting enzyme (ICE). Cystatins are endogenous inhibitors of cysteine protease activities.

Aspartyl Proteases

Peptide bond lysis by aspartyl proteases is achieved through the coordination of a water molecule between two highly conserved aspartate residues. Human aspartyl protease enzymes include members of the pepsin, cathepsin, and renin families. The target for HIV protease inhibitors (e.g., indinavir, ritonavir) is also an aspartyl protease.

Metalloproteases

Members of this protease family, commonly referred to as matrix metalloproteinases (MMPs), include approximately 25 Zn²⁺ dependent enzymes subclassified by their reactivity to collagen, gelatin, and other extracellular matrix proteins. MMPs play a multitude of roles in wound healing and repair, pathogen defense, cancer metastasis, and rheumatoid arthritis. Control of MMP activity is exercised by a group of four proteins referred to as tissue inhibitors of matrix metalloproteases (TIMPs).

Ubiquitin-Proteasome System

Ubiquitin is a highly conserved 76-amino acid polypeptide containing seven lysine residues encoded by four human genes. Proteins may be modified by a single ubiquitin moiety, or multiple molecules may be added to the original ubiquitin. Limited ubiquitination of target proteins generally modifies their subcellular location or intermolecular interactions. Polyubiquitination targets the protein for destruction. Proteolysis occurs in the 26S proteasome, consisting of a 20S catalytic and 19S regulatory subunit constructed from greater than 60 polypeptides.

Proteins in Human Serum and Plasma

The circulating proteome is a complex mixture of thousands of gene products. The 12 most abundant proteins represent more than 95% of total protein mass. Albumin alone represents more than 50% of the total mass of protein and an even higher proportion of the number of molecules, so that albumin is the main contributor to colloid osmotic pressure (oncotic pressure). [Table 18.3](#) lists the 30 most abundant

TABLE 18.2 Selected Members of the Four Protease Families

Protease/Family	Gene Loci	Tissue Expression	Subcellular Localization	Substrate, Function, Pathology
Serine				
Corin	4p13	Broad	Plasma membrane	Natriuretic peptides (heart failure)
Trypsin	7q34	Pancreas	Secreted	Promiscuous (cleavage of LYS-X, ARG-X)
Chymotrypsin	16q23	Pancreas	Secreted	Promiscuous (cleavage of TRP-X, PHE-X, TYR-X)
Neutrophil elastase	19p13	Myeloid cells	Cytoplasm, secreted	Promiscuous (cleavage of VAL-X, ALA-X)
Factor IX	Xq27	Liver	Secreted, plasma membrane	Conversion of factor X to Xa (hemophilia B)
Activated protein C	2q14	Liver		Factor V _a , factor VIII _a (coagulopathy)
PSA (kallikrein)	19q13	Prostate	Secreted	Semen liquefaction; marker of prostate mass and cancer
C1s	12p13	Broad	Secreted	Complement C1r, C2, and C4 (angioedema)
Cysteiny				
Caspase-3	4q34	Broad	Cytosol, nucleus, mitochondria	ASP-X-X-ASP (apoptosis)
Cathepsin C	8p23	Broad	Lysosome	Amyloid precursor (Alzheimer disease)
Aspartyl				
Renin	1q32	Ovary, broad	Secreted	Angiotensinogen (hypertension)
Pepsin	6p21	GI tract, lung	Secreted	Cleavage at adjacent hydrophobic residues (PHE-VAL, ALA-LEU, LEU-TYR)
Presenilin	14q24	Broad	Endoplasmic reticulum/Golgi	Amyloid precursor (Alzheimer disease)
Metallo				
ADAMTS13	9q34	Liver, erythroid precursors, broad	Secreted	von Willebrand factor (thrombotic thrombocytopenic purpura)
MMP-1	11q22	Muscle	Secreted	Collagen (tissue remodeling, embryogenesis, metastasis)
Angiotensin I-converting enzyme	17q23	Testes, broad	Secreted	Angiotensin I (hypertension)

proteins by mass and molecular abundance. An exhaustive list of the contents of the circulating proteome would exceed 12,000 entries.

The range of protein concentrations measured in clinical assays spans more than 10 orders of magnitude and thus poses a significant analytic challenge. In decreasing order of abundance, the source of circulating proteins include (1) proteins secreted directly into plasma, (2) proteins associated with the cell membrane and shed into the circulation, (3) secretory proteins in exocrine secretions, (4) high-abundance cytoplasmic proteins, (5) low-abundance cytoplasmic proteins, (6) transmembrane proteins, and (7) organellar proteins that must traverse more than one membrane to exit cells. Many of these serve as useful markers of physiology and disease.

Circulating concentrations of proteins depend not only on rates of production and efficiency of entry to the circulation but also on rates of clearance. Proteins and peptides substantially smaller than albumin are cleared from the circulation by glomerular filtration, unless they are bound to larger carrier molecules. Other proteins and bioactive peptides are cleared by receptor-mediated uptake or degraded by peptidases.

For all circulating proteins, the choice of measurement using plasma or serum is not without consequence. Plasma

refers to the fluid portion of blood in the presence of an anticoagulant after the cells are removed by centrifugation. Common anticoagulants include heparin, ethylenediamine tetraacetic acid (EDTA), or solutions containing citrate. Small molecular weight additives such as EDTA may introduce osmotic effects on plasma volume, and citrate solutions introduce some specimen dilution. Serum is the fluid component of blood after it is allowed to clot. It differs from plasma in several respects. An approximate 4% decrease in total protein content is related mainly to removal of fibrinogen during coagulation. Intact clotting factors are consumed during the clotting process, and in their place, proteolytic fragments and the contents of platelet granules produced by the clotting process may be recovered in serum.

Abundant Components of the Circulating Proteome

Prealbumin (Transthyretin)

Prealbumin (molecular weight, 35 kDa) transports 10% of circulating triiodothyronine (T₃) and thyroxine (T₄). Prealbumin concentrations are often used as an indicator of adequacy of protein nutrition because of its relatively short half-life (~2 days), and high content of essential amino acids.

TABLE 18.3 High-Abundance Plasma Proteins

RANKED BY MASS ABUNDANCE (MG/L)			RANKED BY MOLECULAR ABUNDANCE (μMOL/L)	
Rank	Protein	Concentration	Protein	Concentration
1	Albumin	35,000–52,000	Albumin	500–800
2	Immunoglobulin G	7000–16,000	Immunoglobulin G	40–120
3	Transferrin	2000–3600	Apolipoprotein A-I	30–70
4	Immunoglobulin A	700–4000	Apolipoprotein A-II	30–60
5	α ₂ -Macroglobulin	1300–3000	Transferrin	25–45
6	Fibrinogen	2000–4000	α ₁ -Antitrypsin	18–40
7	α ₁ -Antitrypsin	900–2000	Haptoglobin	6–40
8	Apolipoprotein A-I	910–1940	α ₁ -Acid glycoprotein	15–30
9	C3	900–1800	α ₂ HS-glycoprotein	9–30
10	IgM	400–2300	Immunoglobulin A	5–30
11	Haptoglobin	300–2000	Hemopexin	9–20
12	Apolipoprotein B	600–1550	Apolipoprotein C-III	6–20
13	α ₁ -Acid glycoprotein	500–1200	Fibrinogen	5–18
14	α ₂ HS-glycoprotein	400–1300	Gc-globulin	8–14
15	Hemopexin	500–1150	Apolipoprotein C-I	6–12
16	Gc-globulin (vitamin D-BP)	400–700	C3	5–10
17	Factor H	240–740	α ₁ -Antichymotrypsin	4–9
18	α ₁ -Antichymotrypsin	300–600	Apolipoprotein D	2–10
19	Inter-α-trypsin inhibitor	200–700	Prealbumin	4–8
20	Apolipoprotein A-II	260–510	β ₂ -Glycoprotein I	3–6
21	C4b-binding protein	200–530	Apolipoprotein A-IV	3–6
22	Ceruloplasmin	200–500	Apolipoprotein C-II	2–7
23	Factor B	180–460	Serum amyloid A4	3–6
24	Prealbumin	200–400	Inter-α-trypsin inhibitor	3–5
25	Gelsolin	200–400	Antithrombin III	3–5
26	Fibronectin	300	α ₁ B-glycoprotein	3–5
27	C1 inhibitor	190–370	Gelsolin	3–5
28	C4	100–400	Ceruloplasmin	2–5
29	Plasminogen	150–350	Factor H	2–5
30	Antithrombin	170–300	Factor B	2–5

Data from Hortin, G. L., Sviridov, D., & Anderson, L. (2008). High-abundance polypeptides of the human plasma proteome comprising the top 4 logs of polypeptide abundance. *Clinical Chemistry*, 54, 1608–1616.

When compared with albumin, prealbumin is a minor component of plasma but a proportionately greater component of CSF. Prealbumin is most commonly assessed using immunonephelometric or immunoturbidimetric methods. See [Chapter 15](#) for additional information on these techniques.

Albumin

The name *albumin* (L. *albus*, meaning white) originated from the white precipitate formed during the boiling of acidic urine from patients with proteinuria. Albumin has a molecular weight of approximately 66 kDa, circulates with a half-life of 15 to 19 days, and is the most abundant plasma protein from the fetal period onward. It plays a major role in the maintenance of colloid osmotic pressure and serves as a transporter for a diverse range of substances such as fatty acids, bilirubin, and drugs. Most clinical laboratories assay albumin in plasma or serum samples by dye-binding methods, which rely on a shift in the absorption spectrum of dyes such as bromocresol green (BCG) or purple (BCP) upon albumin binding. BCP generally is slightly more specific for albumin and yields lower values than BCG, particularly for patients with kidney failure.

α₁-Antitrypsin

AAT is a serpin and is also known as α₁-proteinase inhibitor (Pi). AAT is synthesized by hepatocytes as a single polypeptide chain with 394 amino acid residues and 3 N-linked oligosaccharides, yielding a total molecular weight of approximately 51 kDa. AAT deficiency affects 1 in 3000 to 5000 in the United States, resulting in liver disease and pulmonary disease. Assessment of circulating AAT concentrations is usually performed by immunoturbidimetry or immunonephelometry. Concentrations typically range from 70 to 200 mg/dL (14 to 50 μmol/L) in healthy adults but are higher in patients with inflammatory disorders, malignancy, or trauma, and in women who are pregnant, on estrogen therapy, or taking oral contraceptives.

Ceruloplasmin

Ceruloplasmin (Cp) has a molecular weight of 132 kDa and contains about 95% of serum copper. Failure to incorporate copper into Cp results in an unstable protein and is the cause of Wilson disease.

TABLE 18.4 Inherited Deficiencies of Complement Components

Component	Frequency of Deficiency	Associated Disorders
Ficolins 1-3	Rare?	Recurrent infection
MBP	5%	Infection in infancy; less effect on adults
MASP	Rare?	Recurrent infection (e.g., pneumococcal); inflammation
C1q ^a	Relatively rare	SLE; DLE; GN
C1r, C1s	Rare	SLE; DLE; infection
C2	≥0.0003% (homozygous)	Recurrent infection, vasculitis; SLE, DLE (no antinuclear antibody); half of affected individuals are asymptomatic
C3	Rare	Severe and recurrent bacterial infection, especially with encapsulated, pyogenic bacteria
C4a	13% (heterozygous)	SLE, DLE
C4b	13% (heterozygous)	IgA nephropathy; infection
Combined C4	35% one null; 8%–10% 2 nulls; ≈1% 3 nulls; <0.1% 4 null alleles	Total deficiency: SLE, GN, DLE (many are anti-dsDNA negative but anti-Ro/SSA positive)
C5-C9	Rare	Severe or recurrent infection with <i>Neisseria</i> species
Properdin	Rare	Xlinked; neisserial infection
Factor D	Rare	Recurrent infection
Factor H or I	Rare	Hypercatabolism of C3; recurrent bacterial infection; HUS in factor H deficiency
C1 inhibitor	0.002%	Hereditary angioedema (autosomal dominant)
Decay accelerating factor (DAF, CD 55)	Rare	PNH related to decreased DAF and CD59 on cell surfaces

^aBoth quantitative and qualitative (functional) deficiencies reported.

DLE, Discoid lupus erythematosus; GN, glomerulonephritis; HUS, hemolytic-uremic syndrome; MBP, mannan-binding protein; PNH, paroxysmal nocturnal hematuria; SLE, systemic lupus erythematosus (or SLE-like disease).

Data from Colten, H. R., & Rosen, F. S. (1992). Complement deficiencies. *Annual Review of Immunology*, 10, 809–834; and Unsworth, D. J. (2008). Complement deficiency and disease. *Journal of Clinical Pathology*, 61, 1013–1017.

cascade. Smaller fragments typically serve as anaphylatoxic or chemotactic peptides. All three pathways converge at the C3 convertase, which triggers the formation of the C5 convertase and formation of a membrane attack complex (MAC) consisting of components C5 to C9. The MAC forms an ion channel in the membrane of the foreign pathogen triggering lysis and destruction of the target organism. Clinical disorders of inherited complement deficiency are listed in [Table 18.4](#).

Immunoglobulins

Immunoglobulins (antibodies) are generated against foreign immunogens to initiate clearance of the foreign molecule or organism. Human immunoglobulins (commonly depicted in the shape of a Y, [Fig. 18.7](#)) consist of two identical heavy (H) chains and two identical light (L) chains. Each of the four chains has one variable and one or more constant domains. The variable domains contain the antigen-binding regions and the constant domains of the heavy chains contain sites for complement activation and receptor binding. Cleavage of immunoglobulins with pepsin or papain yields antigen-binding fragments (F_{ab}) and constant region fragments (F_c). Variations in the constant domains of heavy chains (F_c region) result in the classes and subclasses into which immunoglobulins are grouped: IgM, IgG (four subclasses), IgA (two subclasses), IgD, and IgE, respectively. Light chains, which are produced independently and in slight excess of heavy chains, are of two types—kappa (κ) and lambda (λ).

Fig. 18.7 Schematic of basic antibody structure depicting the arrangement of heavy (H) and light (L) chains, as well as respective variable (V) and constant (C) regions. Selective proteolytic digestion yields the F_{ab} fragment that contains antigen-binding sites and the F_c region.

Individual Immunoglobulins and Light Chains

Immunoglobulin G. Immunoglobulin G (IgG) is produced by mature B cells (plasma cells) and accounts for 70% to 75% of the total immunoglobulin in plasma. IgG has a molecular weight of approximately 150 kDa and migrates broadly in the γ - and β -regions on gel electrophoresis. IgG has four

Fig. 18.8 Serum immunoglobulin concentrations as percent of mean adult concentrations before birth and for the first year of life. *IgA*, Immunoglobulin A; *IgG*, immunoglobulin G; *IgM*, immunoglobulin M.

subclasses: IgG_1 , IgG_2 , IgG_3 , and IgG_4 . IgG_1 is the principal IgG to cross the placenta, and neonatal concentrations are similar to maternal concentrations (Fig. 18.8). Neonates have low production of IgG as the result of immaturity of their immune systems, and IgG concentrations fall through infancy as maternally acquired antibody is cleared.

Immunoglobulin M. Immunoglobulin M (IgM) is produced at earlier stages of B-cell development. In the immature immune systems of neonates, IgM is the major immunoglobulin synthesized. In adult serum, it is the third most abundant immunoglobulin, usually accounting for 5% to 10% of total circulating immunoglobulins. Membrane-bound IgM may be found as a component of the B-cell receptor, while circulating IgM is a pentamer containing five monomers linked via disulfides to the small J (joining) chain. The high molecular weight of pentameric IgM (970 kDa; approximately 10% carbohydrate) prevents its ready passage into extravascular spaces. IgM is not transported across the placenta and therefore is not involved in hemolytic disease of neonates. It activates complement more efficiently than IgG .

Immunoglobulin A. Immunoglobulin A (IgA) has a molecular weight of 160 kDa, including about 10% carbohydrate. IgA accounts for about 10% to 15% of serum immunoglobulin and has a half-life of 6 days. IgA is an important component of mucosal immunity. Secretory IgA is found in tears, sweat, saliva, milk, and colostrum, as well as gastrointestinal (GI) and bronchial secretions.

Immunoglobulin D. Immunoglobulin D (IgD) accounts for less than 1% of serum immunoglobulin. It is monomeric, contains about 12% carbohydrate, and has a molecular weight of 184 kDa. Its structure is similar to that of IgG . Similar to IgM , IgD is a surface receptor for antigen on B lymphocytes, but its primary function is unknown.

Immunoglobulin E. Immunoglobulin E (IgE) contains 15% carbohydrate and has a molecular weight of 188 kDa. IgE is so rapidly and firmly bound to specific IgE receptors on mast cells that only small amounts of it are normally present in serum. IgE binds to mast cells via its F_c region. When the antigen (allergen) cross-links two of the attached IgE molecules,

the mast cell is stimulated to release histamine and other vasoactive amines that increase vascular permeability and smooth muscle contraction, mediating type 1 hypersensitivity reactions such as hay fever, asthma, urticaria, and eczema. IgE molecules specific for particular allergens are analyzed to identify the source of allergies. The total serum concentration of IgE may be increased in individuals with allergic disorders.

Free Immunoglobulin Light Chains. Light chains are usually synthesized in slight excess of heavy chains to ensure the assembly of intact immunoglobulins. Consequently, small amounts of free light chain, representing only about 0.1% of total immunoglobulin, are present in serum or plasma. Free κ -light chains (23 kDa) are cleared faster than free λ -light chains, so the plasma concentration of free λ -light chains is usually higher, except in renal failure. Immunoassays specific for free light chains are often used to detect plasma cell disorders.

Clinical Utility Of Immunoglobulin Measurement

Serum normally contains a diverse, polyclonal mixture of antibodies. Disease may be associated with a decrease or an increase in normal polyclonal immunoglobulins, or an increase in one or more monoclonal immunoglobulins. These disease states are detailed below.

Immunoglobulin Deficiency. The diagnosis of major deficiencies in immunoglobulin production is important to avoid infection. Severe combined immune deficiency (SCID) is a B-cell disorder affecting 1 in 100,000 newborns, resulting in broad-spectrum immunoglobulin deficiency. More common primary deficiencies involve only one or two immunoglobulin classes or subclasses. IgA deficiency occurs in about 1 in 500 whites but much less frequently in Asian populations. IgA deficiency may lead to false-negative assays for celiac disease detection, and some affected individuals are at risk for anaphylaxis if they receive blood products containing IgA . Selective deficiency of IgG subclasses is not rare, but it is unclear whether it is an important risk for infection.

Infants have transient physiologic deficiency of IgG , with a nadir at about 3 months of age (Fig. 18.8). Prolonged or severe deficiency may be associated with increased infection rates.

TABLE 18.5 Monoclonal Immunoglobulins (Paraproteins) in Multiple Myeloma

Plasma Paraprotein	Incidence ^a (%)	Mean Age of Occurrence ^a (year)	Incidence of Free Light Chain in Urine (%)	Comments
IgG	50	65	60	Patients more susceptible to infection; paraproteins reach highest concentrations
IgA	25	65	70	Tend to have hypercalcemia and amyloidosis
Free light chain only	20	56	100	Often renal failure; bone lesions; amyloidosis; poor prognosis
IgD	2	57	100	90% λ type; often have extraosseous lesion, amyloidosis, renal failure; poor prognosis
IgM	1	—	100	May or may not have hyperviscosity syndrome
IgE	0.1	—	Most	—
Biclonal	1	—	—	—
None detected	<1	—	0	Usually reduction of normal immunoglobulins; increased plasma cells in bone marrow biopsy

^aApproximate.

Ig, Immunoglobulin.

Concentrations of maternal IgG, transferred across the placenta, rise rapidly in the fetus during the last half of pregnancy, but then drop over a few months after birth. Two groups of neonates are at risk for clinically significant IgG deficiency: premature infants who begin life with less maternal IgG and infants with delayed initiation of IgG synthesis. Monitoring of IgG concentrations can identify this problem. Rising IgM and normal salivary IgA concentrations at 6 weeks of age suggest a favorable prognosis.

Polyclonal Hyperimmunoglobulinemia. Polyclonal increases in plasma immunoglobulins are the normal response to infection. IgG predominates in autoimmune responses. IgA is increased in skin, gut, respiratory, and renal infections, and IgM is increased in primary viral infections and bloodstream infection. Chronic bacterial infection may cause increased concentrations of all immunoglobulins. Measurements of total and allergen-specific IgE are used in the management of asthma and other allergic conditions, especially in children.

Monoclonal Immunoglobulins (Paraproteins). A single clone of plasma cells produces immunoglobulin molecules with a single defined amino acid sequence. If the clone expands greatly, it may produce a discrete band on electrophoresis, often referred to as an M-spike or M-protein. These monoclonal immunoglobulins, termed **paraproteins**, may be polymers, monomers, individual immunoglobulin chains such as free light chains or heavy chains, or fragments of immunoglobulins. Clinical, epidemiologic, and biochemical characteristics of monoclonal paraprotein diseases are summarized in [Table 18.5](#). Up to 25% of paraproteins are benign and have been termed **monoclonal gammopathy of undetermined significance (MGUS)**. The incidence of MGUS increases with age, with 1% incidence for people 50 to 70 years of age and 3% incidence for people older than 70. The occurrence of MGUS is associated with increased risk of progression to **multiple myeloma**.

The primary clinical interest in identifying paraproteins is to detect or monitor proliferative disorders of B cells. Many patients with paraproteins have nonspecific presentations such as anemia or infection. Identification of paraproteins

in serum usually is based on serum protein electrophoresis and immunofixation electrophoresis (IFE; described in a later section). Urine protein electrophoresis and urine IFE are helpful mainly in identifying patients with free immunoglobulin light chains. Urinary free light chains are referred to as **Bence-Jones proteins**. From the laboratory standpoint, paraproteins are often an unpredictable source of interference with many assays. Paraproteins may aggregate or precipitate, causing interference in a variety of photometric reactions and in light-scattering hematology analyzers.

Acute Phase Response

Systemic inflammation in response to infection, tissue injury, or inflammatory disease triggers changes in hepatic production of multiple plasma proteins, as indicated in [Box 18.1](#). This process has been termed the **acute-phase response (APR)**. It is a nonspecific reaction to inflammation, analogous to the increase in temperature or leukocyte count. Plasma concentrations of individual acute-phase proteins rise at different rates, and all reach maxima within 2 to 5 days after an acute insult.

Methods for Analyzing Proteins

Determination of Total Protein

Plasma normally contains about 6.5 to 8.5 g/dL protein, and serum about 4% less. Determination of total protein in biologic fluids in some respects represents a greater challenge than analysis of a specific protein because variable protein composition of biologic fluids leads to variable carbohydrate composition, charge, and physical characteristics of proteins in the mixture. Many methods have been developed to measure the total protein content of biologic fluids, and several are reviewed here.

Kjeldahl Method. This method is rarely used in clinical laboratories but is of historical importance and is sometimes used as a reference method. In this method, protein nitrogen is converted to ammonium ion, which is subsequently measured via titration. Nonprotein nitrogen, such as that from urea and amino acids, also is measured, so a protein

BOX 18.1 Acute Phase Response: Changes in Plasma Protein Concentrations

Positive Acute Phase Response

C-reactive protein (extreme)
 Serum amyloid A (extreme)
 α_1 -Acid glycoprotein
 α_1 -Antitrypsin
 α_1 -Antichymotrypsin
 Antithrombin III
 C3, C4, and C9
 C1 inhibitor

precipitation step may be included. The Kjeldahl method was one of the first methods used for reproducible total protein measurement, but it is time consuming and impractical for routine use. This method has been used to assign values to reference materials for the biuret method.

Biuret Method. Under strongly alkaline conditions, Cu^{2+} ions form multivalent complexes with peptide bonds in proteins. Binding shifts the absorption spectrum of Cu^{2+} ions to shorter wavelengths, leading to a color change from blue to violet that has been termed the *biuret reaction*. Absorbance attributable to protein is measured spectrophotometrically at 540 nm. In general, the biuret reaction reacts equally with all proteins and peptides longer than two amino acids.

Direct Optical Methods. Absorbance of ultraviolet (UV) light between 200 to 225 nm and 270 to 290 nm has been used to measure protein concentrations and is commonly applied to monitor chromatographic separations of peptides

and proteins. Absorbance at 280 nm depends primarily on the tryptophan and tyrosine content of a protein. This technique works best for purified proteins. From 200 to 225 nm, peptide bonds are chiefly responsible for UV absorbance. Absorptivity by proteins at these shorter wavelengths is 10 to 30 times greater than at 280 nm. Many low molecular weight compounds such as urea also have absorbance at wavelengths below 220 nm. Accurate measurement of proteins by this method may require removal of low molecular weight molecules before absorbance measurements are performed.

Dye-Binding Methods. Dye-binding methods depend on shifts in the absorbance spectra of dyes when they bind to proteins. Variable binding of dyes to different proteins is a limitation. Calibration with a protein mixture is particularly difficult to define consistently. Calibration with a pure protein such as albumin may not simulate binding to the complex mixture of proteins in serum or plasma. Coomassie blue binds to polypeptide chains under acidic conditions, resulting in increased absorbance at 595 nm. Some dyes offer sensitivity at lower protein concentrations. Pyrogallol red, for instance, is commonly used to detect total protein in urine and CSF.

Lowry (Folin-Ciocalteu) Method. The detection limit of the Lowry method is about 100 times lower than that of the biuret method. In this technique, specimens are mixed with an alkaline copper solution followed by the addition of the Folin-Ciocalteu reagent. The components of this reagent, phosphotungstic acid and phosphomolybdic acid, are reduced when complexed with peptide, resulting in increased absorbance between 650 and 750 nm.

Refractometry. Refractometry is a method used to rapidly estimate protein at high concentrations. Accuracy decreases at protein concentrations below 3.5 g/dL, where salts, glucose, and other low molecular weight compounds have a larger proportional effect on refractive index. Refractometry is used more often in clinical laboratories to assess the concentration of solutes in urine specimens than for determining total protein.

Light-scattering Methods. Many different reagents have been used to aggregate protein for turbidimetric or nephelometric assays, including trichloroacetic acid, sulfosalicylic acid, benzethonium chloride, and benzalkonium salts under alkaline conditions. Precipitation methods for total protein assays depend on forming a suspension of uniform, insoluble protein particles, which scatter incident light. Albumin and globulins often give different reactivities in precipitation methods.

Variables Affecting Measured Total Protein Concentrations. Biuret methods are commonly calibrated with bovine or human albumin. Protein mixtures with specific albumin-to-globulin ratios are recommended for calibrating other methods. Using these calibration schemes, the total protein concentration of plasma obtained from healthy ambulatory adults is typically 6.5 to 8.5 g/dL. Serum usually contains a protein concentration about 0.3 g/dL less because of the content of fibrinogen and other proteins removed during clotting. Hemodilution and dehydration, along with a change in position (standing vs. recumbent), alter plasma protein concentration. Assuming a recumbent position decreases total protein concentration by 0.3 to 0.5 g/dL. This reflects fluid

Fig. 18.9 Schematic of protein migration and regional annotation in serum protein electrophoresis. The anode is depicted on the left and cathode on the right. Blue shading represents the relative protein concentration (darker is higher) in each region in a normal individual.

redistribution, resulting in dilution of a constant amount of plasma protein in a larger volume.

Nephelometry and Turbidimetry

Nephelometric and turbidimetric methods rely on light scattering by antigen–antibody complexes. For additional information on these two techniques and the difference between them, refer to [Chapter 15](#). Limits of detection of approximately 10 mg/L can be achieved with these methods using antibodies in solution. Binding antibodies to particles of latex or other materials enhances light scattering and can lower limits of detection by 10- to 100-fold. Nephelometric and turbidimetric assays commonly offer within-run coefficients of variation (CVs) of less than 5%, except as limits of detection are approached. Turbidimetric methods can be applied on most automated chemistry analyzers capable of performing photometric methods. Nephelometry requires instrumentation capable of measuring light scattering at an angle to the incident light.

Electrophoresis

Electrophoresis is used to separate proteins by charge. Electrophoretic techniques commonly performed in clinical laboratories include nondenaturing electrophoresis on cellulose acetate strips or agarose gels, capillary electrophoresis (CE), immunofixation, and “Western blotting.” Protein separation in one or two dimensions with polyacrylamide gel is a powerful separation technique frequently used for research.

Serum Protein Electrophoresis. An idealized representation of serum protein electrophoresis is shown in [Fig. 18.9](#). Serum is generally used for electrophoresis of proteins on agarose gels to avoid the fibrinogen in plasma that migrates at the β - γ interface. Highly abundant proteins within gels are visualized with a variety of dyes, including amido black, Ponceau S, acid violet, and Coomassie blue. Quantitation of individual bands can be done using densitometry if the total protein concentration of the sample is known. CE works differently by detecting proteins using the absorbance of proteins at wavelengths below 220 nm.

The major clinical application of serum protein electrophoresis is the detection of monoclonal immunoglobulins (paraproteins) to assist in the diagnosis and monitoring of multiple myeloma and related disorders. Most monoclonal immunoglobulins are observed in the β -region or γ -region. Quantitation of monoclonal components serves as a means of monitoring disease progression and response to therapy. Protein electrophoresis is also informative in other clinical circumstances. Changes in the α_1 -region are typically

related to AAT. Changes in the α_2 -region usually relate to changes in Hp and α_2 macroglobulin (AMG). Bands in the β -region are related to transferrin, C3, and low-density lipoprotein (apolipoprotein B). An increase between β - and γ -bands, so-called bridging of β - and γ -bands, suggests an increase in IgA, as seen with cirrhosis, respiratory tract or skin infection, and rheumatoid arthritis. Finally, increases or decreases in the γ -region suggest changes in immunoglobulins. [Fig. 18.10](#) provides multiple examples of serum electrophoretic patterns in normal and pathologic specimens

Immunofixation Electrophoresis. IFE employs antisera targeted to specific immunoglobulins prior to protein staining. IFE serves as a more sensitive method to detect monoclonal expansion of immunoglobulins and also serves to identify the type of heavy and light chain produced. Examples of IFE from two patients with monoclonal gammopathies are shown in [Fig. 18.11](#).

Western Blotting. For Western blotting, proteins separated on a gel are transferred by electroblotting onto a membrane made of nitrocellulose or polyvinylidene fluoride. Proteins bound on the membrane are identified with specific antibodies conjugated to enzymes such as peroxidase or alkaline phosphatase that act on photometric, fluorescent, or chemiluminescent signaling molecules.

Mass Spectrometry. Multiple types of MS instrumentation provide qualitative or quantitative information about proteins contained in a complex mixture of other molecules. Ionization of peptides and proteins may be accomplished by electrospray or MALDI sources. Electrospray is better suited to analyzing small peptides than larger intact proteins. After ionization, proteins can be separated by quadrupoles, ion traps, time of flight, and other types of mass analyzers. Use of tandem MS with an intermediate fragmentation step between two stages of MS separation offers high sensitivity and specificity for the quantitative analysis of peptides, as it does for most small molecules.

Advantages of using MS for quantitative analysis include the ability to analyze components without developing specific antibodies, and the ability to multiplex a large number of measurements. MS can provide information about post-translational modifications that is difficult to assess by immunoassays and chromatographic or electrophoretic techniques. Examples of clinical applications include identification of genetic variants of prealbumin and CDT. The use of MS is likely to increase for accurate determination of protein concentrations, as recently applied for standardization of hemoglobin A_{1c}, insulin, and C-peptide.

Fig. 18.10 Electrophoretic patterns typical of normal conditions and of some pathologic conditions (agarose gel). The upward- and downward-pointing arrows indicate increase and decrease from the reference interval, respectively. Right- and left-slanting arrows indicate variation from normal to an increase or from normal to a decrease from the reference interval, respectively. Proteins in Other Body Fluids

Complex mixtures of proteins are present in all biologic fluids; analysis of a variety of other specimens is diagnostically useful, including analyses of urine, CSF, pleural and peritoneal fluids, amniotic fluid, saliva, and feces.

Saliva

Saliva is an ultrafiltrate of plasma that contains a unique set of proteins derived from the salivary glands. Protein composition varies with the site and method of sampling. In addition to the well-known presence of amylase, proteomic approaches have detected sequence from hundreds of different proteins in saliva. Proteins involved in host defense, such as immunoglobulins, lysozyme, and lactoferrin, are also particularly abundant. Efforts are underway to exploit the salivary proteome to detect and characterize susceptibility to dental caries, periodontal disease, head and neck cancers, diabetes, and cystic fibrosis. Interrogation of saliva for the presence of secretory IgA is common in the diagnostic workup of hypogammaglobulinemia.

Cerebrospinal Fluid

CSF is the extracellular fluid around the brain and spinal column. CSF usually has total protein concentrations about 100-fold lower than plasma and a different protein composition because most proteins have limited passage across the blood–brain barrier. CSF is typically obtained by a spinal tap in the lumbar region. The blood–brain or blood–CSF barrier limits exchange of large compounds, so low to intermediate molecular weight plasma proteins such as prealbumin, albumin, and transferrin normally predominate in CSF. Analyses of total protein and specific proteins in CSF are employed to detect increased permeability of the blood–CSF barrier, increased intrathecal synthesis, or increased release of proteins from neural and glial tissue. Conditions such as viral meningitis, encephalitis, increased intracranial pressure, trauma, and hemorrhage may all compromise the blood–brain barrier,

resulting in increased CSF protein. Protein concentrations associated with these conditions are displayed in Table 18.6. Increased intrathecal synthesis of immunoglobulins, particularly IgG, occurs in demyelinating diseases of the CNS, especially multiple sclerosis.

Total Protein in Cerebrospinal Fluid. The total protein concentration in CSF is an indicator of blood–CSF permeability. The protein concentration of CSF usually is more than 100-fold lower than plasma, so methods with greater sensitivity or increased specimen volume are required for CSF applications. Methods commonly used by clinical laboratories to measure total CSF protein include (1) pyrogallol red, (2) benzethonium chloride, (3) reverse-biuret, and (4) biuret. The reverse-biuret method measures free copper remaining after formation of biuret complexes by reduction and complexation with a chelating dye. Analyzers often use the same method, possibly with some adjustment of specimen volume, for CSF and urine protein. The usual reference interval for CSF total protein in adults is 15 to 45 mg/dL. Total CSF protein concentrations are considerably higher in neonates and in healthy elderly adults. In CSF from premature and full-term neonates, concentrations up to 400 mg/dL are observed. In term newborns, a progressive decline in CSF protein is seen over the first few weeks of life, with values approaching adult concentrations by 4 months of age.

Assessment Of Specific Cerebrospinal Fluid Proteins. The electrophoretic pattern of normal CSF has two striking features—a prealbumin band and two transferrin bands—one at β_2 in addition to the usual β_1 position. As mentioned previously, β_2 -transferrin has decreased charge because its glycosyl chains lack terminal sialic acid residues. Both β_2 -transferrin and another relatively abundant CSF protein, prostaglandin D synthase or β -trace, have been used to determine whether clear fluids from nasal or ear passages represent leakage of CSF—so-called CSF rhinorrhea and otorrhea. CSF immunoglobulin concentrations and oligoclonal immunoglobulin bands on electrophoretic separations of CSF are helpful in the diagnosis of multiple sclerosis and other inflammatory diseases of

TABLE 18.6 Cerebrospinal Fluid Total Protein in Various Diseases

Clinical Condition	Appearance and Cells × 106/L	Total Protein, mg/dL
Normal	Clear, colorless; 0–5 lymphocytes	15–45 ^a
Increased Admixture of Proteins From Blood		
Increased Capillary Permeability		
• Bacterial meningitis	Turbid, opalescent, purulent, usually >500 polymorphs	80–500
• Cryptococcal meningitis	Clear or turbid; 50–150 polymorphs or lymphocytes	25–200
• Leptospiral meningitis	Clear to slight haze; polymorphs early, then 5–100 lymphocytes	50–100
• Viral meningitis	Clear or slight haze, colorless; usually ≤500 lymphocytes	30–100
• Encephalitis	Clear or slight haze, colorless; usually ≤500 lymphocytes	15–100
• Poliomyelitis	Clear, colorless; ≤500 lymphocytes	10–300
• Brain tumor	Usually clear; 0–80 lymphocytes	15–200 (usually normal)
Mechanical Obstruction		
• Spinal cord tumor ^b	Clear, colorless, or yellow	100–2,000
Hemorrhage		
Cerebral hemorrhage	Colorless, yellow, or bloody; blood cells	30–150
Local Immunoglobulin Production		
• Neurosyphilis	Clear, colorless; 10–100 lymphocytes	50–150
• Multiple sclerosis ^c	Clear, colorless; 0–10 lymphocytes	25–50
Both Increased Capillary Permeability and Local Immunoglobulin Production		
• Tuberculous meningitis	Colorless, fibrin clot, or slightly turbid; 50–500 lymphocytes	50–300 (occasionally ≤1000)
• Brain abscess	Clear or slightly turbid	20–120
After myelography (inflammatory reaction)		Slight increase

^aPremature infants: ≤400 mg/dL; children: 30–100 mg/dL; older adults: ≤60 mg/dL.

^bFroin syndrome: Lumbar fluid values are much higher than cisternal fluid values.

^cSimilar values may occur in certain other chronic inflammatory conditions of the nervous system.

the CNS. Myelin basic protein concentrations may be an indicator of myelin turnover in multiple sclerosis. A number of other proteins such as S100B and neuron-specific enolase are potential markers of traumatic or ischemic brain injury. Concentrations of tau and β -amyloid isoforms may be useful in the diagnosis and prognosis of Alzheimer disease.

Peritoneal and Pleural Fluids

Pathologic accumulations of fluid in the peritoneal and pleural cavities or elsewhere vary greatly in protein content. These fluids may be ultrafiltrates with low-protein concentrations relative to plasma and scant amounts of large proteins (transudates). Alternatively, fluids may have protein concentrations approaching those of plasma and significant amounts of large proteins such as immunoglobulins and α_2 macroglobulin in response to local inflammation and increased vascular permeability (exudates).

Distinction between transudates and exudates assists in diagnosing the cause of fluid accumulation. The major cause of pleural transudates is congestive heart failure. Exudates occur with infection, pleuritis, pulmonary embolism, and cancer.

Fecal Material

The use of fecal material for protein analysis is relatively infrequent but indicated in some specific clinical circumstances. Assessment of protein content in feces has a number of limitations. Results of fecal protein content are often normalized to fecal weight. Thus watery stool specimens generally provide decreased estimates of protein concentration. Extraction is likewise dependent on stool consistency and homogeneity, leading to considerable within-subject and between-subject variability.

Protein loss in the GI tract may be assessed using an assay of fecal AAT. The amount of fecal AAT excreted over time is

determined as a function of the serum AAT concentration. Inflammatory bowel disease (IBD) includes Crohn disease and ulcerative colitis. A number of fecal protein markers have been employed as tools for assessment of IBD, Crohn disease, and ulcerative colitis. Fecal products secreted by

white blood cells, such as lactoferrin and calprotectin, have been used as a measure of disease activity in IBD. Exocrine pancreatic disease may be assessed by measurement of proteins such as fecal elastase that are derived from pancreatic secretions.

POINTS TO REMEMBER

Amino acids are more than the backbone of peptides and proteins.

- Amino acids can exist in multiple charged states depending on pH.
- L-Amino acids are the most important biologically active isomers.
- Amino acid metabolites serve as respiratory fuel.
- Amino acid transport is achieved by numerous membrane transport systems.
- Analysis of amino acids allows detection of inborn errors of metabolism.

Peptides

- Larger peptides are processed to form multiple smaller bioactive peptides.
- Peptide bonds form between α -amino and α -carbonyl of successive amino acids.
- Immunoassays often detect mixtures of peptides with variable biologic activity.
- B-Type natriuretic peptide is useful in the diagnosis of heart failure.
- Heparin inhibits mobilization of storage iron.

Proteins

- The primary structure of proteins is the linear sequence of amino acid residues.
- Proteins may be separated by size, electric charge, and differential solubility.
- Protein folding is assisted by molecular chaperones.
- Proteins are posttranslationally modified to alter location and function.
- Protein catabolism is a specific and a highly controlled process.
- The human plasma proteome consists of more than 12,000 entries.

REVIEW QUESTIONS

1. Which of the following amino acids participates in formation of new polypeptide chains?
 - a. Desmosine
 - b. Ornithine
 - c. Histidine
 - d. Taurine
2. Which of the following amino acids is the most hydrophobic at physiologic pH?
 - a. Glutamate
 - b. Lysine
 - c. Isoleucine
 - d. Threonine
3. The pH at which a molecule such as a protein has a net charge of zero is referred to as the:
 - a. isoelectric point.
 - b. dissociation constant.
 - c. isosbestic point.
 - d. solubility point.
4. A paraprotein is a:
 - a. membrane-bound protein.
 - b. denatured/unfolded protein.
 - c. protein-prosthetic group.
 - d. monoclonal immunoglobulin.
5. Which of the following is a ketogenic amino acid?
 - a. Glycine
 - b. Leucine
 - c. Glutamate
 - d. Proline
6. Which of the following is a positive acute-phase reactant?
 - a. Transferrin
 - b. Albumin
 - c. Ferritin
 - d. Prealbumin
7. Covalent modification of proteins with ubiquitin leads to:
 - a. membrane localization.
 - b. catabolism/destruction.
 - c. enhanced activity.
 - d. nuclear localization.
8. The plasma protein that serves to transport a large number of compounds including bilirubin, calcium, drugs, and free fatty acids is:
 - a. prealbumin.
 - b. ceruloplasmin.
 - c. haptoglobin.
 - d. albumin.

9. α_1 Antitrypsin inhibits which class of protease?
 - a. Metalloproteases
 - b. Aspartyl proteases
 - c. Cysteiny proteases
 - d. Serine proteases
10. The most abundant circulating immunoglobulin in adult serum is:
 - a. IgA.
 - b. IgD.
 - c. IgG.
 - d. IgM.

Serum Enzymes

Mauro Panteghini, Renze Bais

OBJECTIVES

1. Define the following and give an example of each type:
 - Hydrolase
 - Phosphotransferase
 - Lyase
 - Transferase
 - Oxidoreductase
2. List the factors that affect enzyme activity and appearance in blood.
3. For each of the following enzymes, state and describe the biochemistry, physiological actions (if known), tissue distribution, clinical significance, method of laboratory analysis (including analytical performance specifications), and possible analytical interferences:
 - 5'-Nucleotidase
 - Aspartate aminotransferase
 - Alanine aminotransferase
 - Creatine kinase (CK)
 - Alkaline phosphatase (ALP)
 - γ -Glutamyltransferase
 - Amylase
 - Lactate dehydrogenase (LDH)
 - Lipase
 - Tartrate-resistant acid phosphatase
 - Serum cholinesterase
4. List the isoenzymes, the clinical significance of the isoenzymes (if any), and methods of laboratory analysis used to assess the isoenzymes of each of the following:
 - ALP
 - LDH
 - Amylase
 - Tartrate-resistant acid phosphatase
 - CK
5. Assess and solve case studies involving serum enzymes and isoenzymes and describe the laboratory methods for their analysis.

KEYWORDS AND DEFINITIONS

α -Amylase An enzyme that catalyzes the hydrolysis of 1,4- α -glycosidic linkages in starch, glycogen, and related polysaccharides and oligosaccharides.

Acid phosphatase All phosphatases with optimal activity below pH 7.0 that catalyze the cleavage of orthophosphate from orthophosphoric monoesters; most of the activity in serum is of a tartrate-resistant type.

Acute pancreatitis A sudden inflammation of the pancreas that is usually accompanied with severe upper abdominal pain.

Aldolase A lyase that catalyzes cleavage of fructose-1,6-diphosphate into dihydroxyacetone-phosphate and glyceraldehyde 3-phosphate in the glycolytic breakdown of glucose to pyruvate.

Alkaline phosphatase A hydrolase that catalyzes the alkaline hydrolysis of a large variety of naturally occurring and synthetic substrates.

Aminotransferases A subclass of enzymes of the transferase class that catalyze the transfer of an amino group from a donor (generally an amino acid) to an acceptor (generally a 2-oxo acid). Most of these enzymes are pyridoxal phosphate proteins. Alanine and aspartate aminotransferase are examples that are of significant clinical utility.

Apoenzyme The protein component of an enzyme.

Cholecystitis A painful inflammation of the gallbladder.

Cholinesterase An enzyme of the hydrolase class that catalyzes the cleavage of the acyl group from various esters of choline, including acetylcholine, and some related compounds.

Coenzyme An organic nonprotein molecule that binds with the protein molecule (apoenzyme) to form the active enzyme (holoenzyme).

Creatine kinase A dimeric transferase enzyme that catalyzes the reversible phosphorylation of creatine by adenosine triphosphate (ATP). Creatine kinase (CK) has four isoenzymes: CK-MM, CK-MB, CK-BB, and mitochondrial CK.

γ -Glutamyltransferase A transferase enzyme that reversibly catalyzes the transfer of a glutamyl group from a glutamyl-peptide and an amino acid to a peptide and a glutamyl-amino acid.

Holoenzyme Active enzyme formed by combination of a coenzyme and an apoenzyme.

Isoenzyme A molecular form that originates at the level of the genes that encode the structures of the enzyme proteins in question.

Isoform An enzyme molecular form that has been posttranslationally modified.

Lactate dehydrogenase An oxidoreductase enzyme that reversibly catalyzes the reduction of pyruvate to (L)-lactate, using NADH (reduced form of nicotinamide adenine dinucleotide) as an electron donor.

Lipase A hydrolase that hydrolyzes glycerol esters of long-chain fatty acid.

5'-Nucleotidase A phosphatase that acts only on nucleoside-5'-phosphates, such as adenosine-5'-phosphate (AMP), releasing inorganic phosphate.

Paget disease A chronic disorder that results in enlarged and deformed bones (also known as osteitis deformans, osteodystrophia deformans).

Prosthetic group A tightly bound, nonpeptide structure required for the activity of an enzyme.

The basic principles of enzyme and rate analyses are discussed in [Chapter 14](#). Individual enzymes of clinical utility are discussed in this chapter. To better clarify their clinical application, the individual enzymes are discussed relative to the organ in which they are clinically most important. However, overlap may occur for this classification, as the same enzyme may be used for investigating disease in different organs.

BASIC CONCEPTS

Injury to tissue releases cellular substances such as enzymes that can be used as plasma markers of tissue damage. For a substance to serve as a biochemical marker of damage to a specific organ or tissue, it must arise predominantly from the organ or tissue of interest. Some enzymes are found predominantly in specialized tissue (e.g., lipase [LIP] in the pancreas); others, more widely distributed, have tissue-specific **isoenzymes** or **isoforms** (e.g., the pancreatic isoenzyme of α -amylase) that can be evaluated to enhance tissue and organ specificity.

In general, laboratory specialists use changes in activity in the serum or plasma of enzymes that are predominantly intracellular and physiologically present in the blood at low concentrations only. Increases in the serum activities of these enzymes are used to infer the location and nature of pathological changes in tissues of the body. Therefore an understanding of the factors that affect the rate of release of enzymes from their cells of origin and the rate at which they are cleared from the circulation is necessary to correctly interpret changes in activity that occur with disease.

Knowledge of the intracellular locations of enzymes can assist in determining the nature and severity of a pathological process if suitable enzymes are assayed in the blood. For instance, a mild inflammation of the liver, such as a mild attack of viral hepatitis, is likely to increase only the permeability of the liver cell membrane while allowing cytoplasmic enzymes to leak out into the blood, but a severe attack causing cell necrosis also disrupts the mitochondrial membrane, and both cytoplasmic and mitochondrial enzymes are detected in the blood. The timing of the enzyme's diagnostic window is another important aspect to be considered when these markers are used to evaluate acute injury. The diagnostic window for an injury marker is the interval of time after an episode of injury during which plasma concentrations of the marker are increased, thereby demonstrating the occurrence of injury.

POINTS TO REMEMBER

The pattern of appearance of an enzyme in blood after an acute injury depends on:

- The intracellular location and whether molecules are bound or free
- Molecular weight (because heavier molecules diffuse at a slower rate)
- Local blood and lymphatic flow
- The rate of elimination from blood

The main enzymes of established clinical value, together with their tissues of origin and their major clinical applications, are listed in [Table 19.1](#).

MUSCLE ENZYMES

Enzymes in this category include **CK** and **aldolase** (ALD).

Creatine Kinase

Creatine kinase (CK) (EC 2.7.3.2; adenosine triphosphate [ATP]: creatine *N*-phosphotransferase) is a dimeric enzyme (82 kDa) that catalyzes the reversible phosphorylation of creatine (Cr) by ATP.

Physiologically, when muscle contracts, ATP is converted to adenosine diphosphate (ADP), and CK catalyzes the rephosphorylation of ADP to ATP using creatine phosphate (CrP) as the phosphorylation reservoir.

Optimal pH values for the forward ($\text{Cr} + \text{ATP} \rightarrow \text{ADP} + \text{CrP}$) and reverse ($\text{CrP} + \text{ADP} \rightarrow \text{ATP} + \text{Cr}$) reactions are 9.0 and 6.7, respectively. Mg^{2+} is an obligate activating ion that forms complexes with ATP and ADP. The optimal

TABLE 19.1 Distribution of Clinically Important Enzymes

Enzyme	Principal Sources of Enzyme in Blood	Principal Clinical Applications
Alanine aminotransferase	Liver	Hepatic parenchymal disease
Alkaline phosphatase	Liver, bone, intestinal mucosa, placenta	Hepatobiliary disease, bone disease
Amylase (pancreatic isoenzyme)	Pancreas	Pancreatic disease
Aspartate aminotransferase	Heart, liver, skeletal muscle, erythrocytes	Hepatic parenchymal disease
Creatine kinase	Skeletal muscle, heart	Muscle disease
γ -Glutamyltransferase	Liver, pancreas, kidney	Hepatobiliary disease
Lactate dehydrogenase	Heart, erythrocytes, lymph nodes, skeletal muscle, liver	Hemolytic and megaloblastic anemias, leukemia and lymphoma, oncology
Lipase	Pancreas	Pancreatic disease

TABLE 19.2 Approximate Concentrations of Tissue Creatine Kinase Activity (Expressed as Multiples of Creatine Kinase Activity Concentrations in Serum) and Cytoplasmic Isoenzyme Composition

Tissue	Relative CK Activity	ISOENZYMES (%)		
		CK-BB	CK-MB	CK-MM
Skeletal muscle (type I, slow twitch, or red fibers)	50,000	<1	3	97
Skeletal muscle (type II, fast twitch, or white fibers)	50,000	<1	1	99
Heart	10,000	<1	22	78
Brain	5000	100	0	0
Gastrointestinal tract smooth muscle	5000	96	1	3
Urinary bladder smooth muscle	4000	92	6	2

CK, Creatine kinase.

concentration range for Mg^{2+} is narrow, and excess Mg^{2+} is inhibitory. Many metal ions, such as Mn^{2+} , Ca^{2+} , Zn^{2+} , and Cu^{2+} , inhibit enzyme activity, as do iodoacetate and other sulfhydryl-binding reagents.

The enzyme in serum is relatively unstable, activity being lost because of sulfhydryl group oxidation at the active site of the enzyme. Activity can be partially restored by incubating the enzyme preparation with sulfhydryl compounds, such as *N*-acetylcysteine, dithiothreitol (Cleland reagent), or glutathione.

Biochemistry

CK activity is greatest in striated muscle and heart tissue, which contain some 2500 and 550 U/g of protein, respectively. Other tissues, such as (1) brain, (2) gastrointestinal tract, and (3) urinary bladder, contain significantly less activity (Table 19.2).

CK is a dimer composed of two subunits (B and M), each with a molecular weight of about 40 kDa. These subunits are the products of loci on chromosomes 14 and 19, respectively. Because the active form of the enzyme is a dimer, only three different pairs of subunits can exist: BB (or CK-1), MB (or CK-2), and MM (or CK-3). The distribution of these isoenzymes in the various tissues of humans is shown in Table 19.2. All three of these isoenzyme species are found in the cytosol of the cell or are associated with myofibrillar structures. However, there exists a fourth form that differs from the others both immunologically and by electrophoretic mobility. This isoenzyme (CK-Mt) is located between the inner and

outer membranes of mitochondria, and it constitutes, in the heart for example, up to 15% of total CK activity. The gene for CK-Mt is located on chromosome 15.

CK activity in serum may also be found in macromolecular form—the so-called macro-CK. It exists in two forms: types 1 and 2. Type 1 is a complex of CK, typically CK-BB, and an immunoglobulin, often IgG. It is not of pathological significance, but it can be the cause of increased CK results, leading to diagnostic confusion and unnecessary further investigation. Prevalence has been estimated between 0.8% and 2.3%, and >80% of individuals positive for macro-CK type 1 (immunoglobulin bound) are female. Macro-CK type 2 is oligomeric CK-Mt, with a reported prevalence of between 0.5% and 2.6% in hospitalized patients. It is found predominantly in adults who are severely ill with malignancy or liver disease, and in children who have notable tissue distress. The appearance of this macro-CK in serum is usually associated with a poor prognosis. Macro-CKs can interfere with the assay of CK-MB by some immunoinhibition methods.

Clinical Significance

CK determination is the preferred laboratory test in cases of suspected muscle damage. Serum CK is increased in nearly all patients when (1) injury, (2) inflammation, or (3) necrosis of skeletal (or heart) muscle occurs.

Increased serum CK activity may be the only sign of subclinical neuromuscular disorders. About 30% to 44% of asymptomatic subjects with persistent hyper-CKemia have myopathy. Serum CK activity is greatly elevated in all types of

muscular dystrophy. In progressive muscular dystrophy (particularly Duchenne sex-linked muscular dystrophy), enzyme activity in serum is highest in infancy and childhood, and may be increased long before the disease is clinically apparent. Serum CK activity characteristically falls as patients get older and as the mass of functioning muscle diminishes with progression of the disease. About 50% to 80% of asymptomatic female carriers of Duchenne dystrophy show a three- to sixfold increase in CK activity. High values of CK (up to 50-fold the upper reference limit [URL] in active disease) are noted in viral myositis, polymyositis, and other inflammatory myopathies. However, in neurogenic muscle diseases, such as (1) myasthenia gravis, (2) multiple sclerosis, (3) poliomyelitis, and (4) parkinsonism, serum enzyme activity is not increased.

In acute rhabdomyolysis caused by crush injury, with severe muscle destruction, serum CK activities exceeding 200 times the URL may be found. In this condition, a very high serum CK, mirroring myoglobinuria and its hem-induced mechanism of renal injury, has been associated with the risk of development of acute renal failure. If the CK remains below 5000 U/L (about 30 times the URL) during the first 3 days after the insult, the probability of developing acute renal failure appears to be low. Serum CK can also be mildly increased by other direct trauma to muscle, including intramuscular injection and surgical intervention. Finally, a number of drugs can increase serum CK activities. The drugs principally responsible are (1) statins, (2) fibrates, (3) antiretrovirals, and (4) angiotensin II receptor antagonists. The clinical spectrum of statin induced myotoxicity includes (1) asymptomatic rise in serum CK activity, (2) myalgia, (3) myositis, and (4) rhabdomyolysis (0.02%). Routine monitoring of CK in asymptomatic patients is not recommended; however, CK must be assessed in patients presenting with muscle pain and weakness, and statin treatment stopped if values increase more than fivefold the URL.

Changes in serum CK and its MB isoenzyme after acute myocardial infarction have been used for diagnosis for many years. However, it is now more clinically appropriate to use more cardiac-specific troponin I or T (see [Chapter 34](#)).

During normal childbirth, a sixfold increase in maternal serum CK activity occurs. Surgical intervention during labor further increases the activity of CK in serum.

Determination of Creatine Kinase Activity

Currently all commercial assays for total CK are based on the reverse reaction ($\text{Cr} \leftarrow \text{CrP}$), which proceeds about six times faster than the forward reaction. CK catalyzes the conversion of CrP to Cr with concomitant phosphorylation of ADP to ATP. The ATP produced is measured by hexokinase (HK)/glucose-6-phosphate dehydrogenase (G6PD)—coupled reactions that ultimately convert NADP^+ to NADPH, which is monitored spectrophotometrically at 340 nm. The assay is optimized by adding (1) *N*-acetylcysteine to activate CK, (2) ethylenediaminetetraacetic acid (EDTA) to bind Ca^{2+} and to increase the stability of the reaction mixture, and (3) adenosine pentaphosphate (Ap_5A) in addition to AMP to inhibit adenylate kinase (AK). The International Federation of

Clinical Chemistry and Laboratory Medicine (IFCC) developed a reference procedure based on this reaction principle for the measurement of CK at 37°C.

Specimens for CK analysis include serum and plasma heparin. Anticoagulants other than heparin should not be used in collection tubes, because they inhibit CK activity. CK activity in serum is relatively unstable and is rapidly lost during storage. Average stabilities are less than 8 hours at room temperature, 48 hours at 4°C, and 1 month at -20°C. Therefore the serum specimen should be chilled to 4°C if the sample is not analyzed immediately, and stored at -80°C if analysis is delayed for longer than 30 days. A moderate degree of hemolysis is tolerated because erythrocytes contain no CK activity. However, severely hemolyzed specimens (free hemoglobin concentration >20 g/L) are unsatisfactory because enzymes and intermediates (AK, ATP, and glucose-6-phosphate) liberated from the erythrocytes may affect the lag phase and side reactions occurring in the assay system.

For a single laboratory, the analytical specifications for desirable performance of CK assays, derived from biological variation of the enzyme, are as follows: imprecision (CV) $\leq 7.3\%$, bias no more than $\pm 8.7\%$, and total error lower than $\pm 20.6\%$.

Serum CK activity is subject to a number of physiological variations. It is influenced by (1) sex, (2) age, (3) race, (4) muscle mass, and (5) physical activity. Men have higher values than women, and blacks have higher values than non-blacks. In white subjects, the reference interval was found to be 46 to 171 U/L for men and 34 to 145 U/L for women when measured with an assay traceable to the IFCC 37°C reference procedure. Newborns generally have higher CK activity, resulting from skeletal muscle trauma during birth. Exercise, particularly if unaccustomed, can increase serum CK activity, which may ascend as high as 10 times the URL within 24 hours of activity.

Separation and Quantification of Creatine Kinase Isoenzymes

Electrophoretic methods are useful for the separation of all CK isoenzymes, but they are no longer routinely used. The isoenzyme bands are visualized by incubating the support (e.g., agarose or cellulose acetate) with a concentrated CK assay mixture using the reverse reaction. NADPH formed in this reaction is then detected by observing the bluish-white fluorescence after excitation by long-wave (360 nm) ultraviolet light. The mobility of CK isoenzymes at pH 8.6 toward the anode is $\text{BB} > \text{MB} > \text{MM}$, with the MM remaining cathodic to the point of application. The discriminating power of electrophoresis also allows the detection of abnormal bands (e.g., macro-CKs).

Immunoassays are applicable to the direct measurement of CK-MB. Immunoinhibition techniques measuring the catalytic activity of the B subunit of CK dimer were first introduced, but now their use should be discouraged for the lack of analytical specificity and sensitivity. Currently the most common approach is to measure concentrations of the CK-MB protein ("mass") by using "sandwich" immunoassays with

monoclonal antibodies specifically recognizing the MB dimer. Mass assays are sensitive with a limit of detection for CK-MB of less than 1 µg/L. With CK-MB mass assays, the URL for males is 5.0 µg/L, with values for females being less than male values.

Aldolase

Aldolase (ALD) (EC 4.1.2.13; D-fructose-1,6-diphosphate D-glyceraldehyde-3-phosphate-lyase) catalyzes the splitting of D-fructose-1,6-diphosphate to D-glyceraldehyde-3-phosphate and dihydroxyacetone-phosphate, an important reaction in the glycolytic breakdown of glucose to pyruvate. ALD is probably present in all cells, although it occurs in particularly large quantities in the muscles, liver, and brain.

Serum ALD determinations have been proposed for diagnosing diseases of skeletal muscle. In general, however, measurement of ALD activity in the serum of subjects with suspected muscle disease does not add information to that available more readily from measurement of CK. Accordingly, ALD measurement within clinical laboratories should be discouraged.

LIVER ENZYMES

Enzymes in this category include (1) alanine **aminotransferase** (ALT), (2) aspartate aminotransferase (AST), (3) alkaline phosphatase (ALP), (4) γ-glutamyltransferase (GGT), and (5) 5'-nucleotidase (NTP). The aminotransferases, ALP and γ-GGT are widely used and available on automated analyzers. They have long been mistakenly considered as a part of "liver function tests." They are not tests of liver function, but the habit sometimes persists.

The most common alterations in liver enzyme activities encountered in clinical practice can be divided into two major pathophysiology subgroups: (1) hepatocellular damage (increased aminotransferase activities) and (2) cholestasis (increased ALP and γ-GGT activities), although certain liver diseases may display a mixed biochemical picture (Fig. 19.1).

Aminotransferases

The aminotransferases constitute a group of enzymes that catalyze the interconversion of amino acids to 2-oxo-acids by transfer of amino groups. AST (EC 2.6.1.1; L-aspartate: 2-oxoglutarate

aminotransferase) and ALT (EC 2.6.1.2; L-alanine: 2-oxoglutarate aminotransferase) are the aminotransferases of clinical interest.

The 2-oxoglutarate/L-glutamate couple serves as one amino group acceptor and donor pair in all amino-transfer reactions; the specificity of the individual enzymes derives from the particular amino acid that serves as the other donor of an amino group. Thus AST catalyzes the following reaction:

ALT catalyzes the analogous reaction as follows:

The reactions are reversible, but the equilibria of the AST and ALT reactions favor formation of aspartate and alanine, respectively.

Pyridoxal-5'-phosphate (P-5'-P) and its amino analogue, pyridoxamine-5'-phosphate, function as **coenzymes** in *in vivo* amino-transfer reactions. The P-5'-P is bound to the inactive **apoenzyme** and serves as a true **prosthetic group**. P-5'-P bound to the apoenzyme accepts the amino group from the first substrate, aspartate or alanine, to form enzyme-bound pyridoxamine-5'-phosphate and the first reaction product, oxaloacetate or pyruvate, respectively. The coenzyme in amino form then transfers its amino group to the second substrate, 2-oxoglutarate, to form the second product, glutamate. P-5'-P is thus regenerated.

Both coenzyme-deficient apoenzymes and **holoenzymes** may be present in serum. Thus the addition of P-5'-P under measurement conditions that allow recombination with the enzymes usually produces an increase in aminotransferase activity. For clinical assays, in accordance with the principle that all factors affecting the rate of reaction must be optimized and controlled, the addition of P-5'-P in aminotransferase assays is recommended to ensure that all enzymatic activity is measured.

Biochemistry

AST is found in the (1) heart, (2) liver, (3) skeletal muscle, and (4) kidney, whereas ALT is found primarily only in the liver and kidney (Table 19.3). ALT is exclusively cytoplasmic, but both mitochondrial and cytoplasmic forms of AST are found in cells. These are genetically distinct AST isoenzymes. About 5% to 10% of the activity of total AST in serum from healthy individuals is of mitochondrial origin.

Fig 19.1 Liver enzymology patterns. ALP, Alkaline phosphatase; ALT, alanine aminotransferase; AST, aspartate aminotransferase; GGT, γ-glutamyltransferase.

TABLE 19.3 Aminotransferase Activities in Human Tissues, Relative to Serum as Unity

	Aspartate Aminotransferase	Alanine Aminotransferase
Heart	7800	450
Liver	7100	2850
Skeletal muscle	5000	300
Kidneys	4500	1200
Pancreas	1400	130
Spleen	700	80
Lungs	500	45
Erythrocytes	15	7
Serum	1	1

Clinical Significance

Liver disease is the most important cause of increased amino-transferase activity in serum and represents the indication for the measurement requests. Although serum activities of both AST and ALT become increased whenever disease processes affect liver cell integrity, ALT is the more liver-specific enzyme. Serum increases of ALT activity are rarely observed in conditions other than parenchymal liver disease. Moreover, increases of ALT activity persist longer than those of AST activity. Thus the incremental benefit of routine determination of AST, in addition to ALT, is limited. Ideally laboratories reporting abnormal ALT results (e.g., >URL) should offer AST as a reflex test and calculate the AST-to-ALT ratio because it provides useful diagnostic and prognostic information (see below).

In most types of liver disease, ALT activity is higher than that of AST; exceptions may be seen in (1) alcoholic hepatitis, (2) hepatic cirrhosis, and (3) liver neoplasia. In viral hepatitis and other forms of liver disease associated with acute hepatic necrosis, serum AST and ALT activities are increased even before the clinical signs and symptoms of disease (e.g., jaundice) appear. Activities for both enzymes may reach values as high as 100 times the URL, although 10-fold to 40-fold increases are most frequently encountered. The most efficient ALT threshold for diagnosing acute liver injury lies at seven times the URL (sensitivity and specificity >95%). Peak values of amino-transferase activity occur between the 7th and 12th days; activities then gradually decrease, reaching physiological concentrations by the 3rd to 5th week if recovery is uneventful. Peak activities bear no relationship to prognosis and may fall with worsening of the patient's condition due to lack of further functional hepatocytes to continue enzyme release.

Persistence of increased ALT for longer than 6 months after an episode of acute hepatitis is used to diagnose chronic hepatitis. ALT has been reported persistently normal in 15% to 50% of patients with chronic hepatitis C, but the likelihood of continuously normal ALT decreases with an increasing number of measurements. Therefore, in patients with acute hepatitis C, ALT should be measured periodically over the next 1 to 2 years to determine if it becomes and stays normal.

An AST-to-ALT ratio greater than or equal to 1 has approximately 90% positive predictive value for diagnosing

the presence of advanced fibrosis in patients with chronic liver disease. Furthermore, the amount of increase in the ratio can reflect the grade of fibrosis in these patients.

Nonalcoholic fatty liver disease (NAFLD) is the most common cause of amino-transferase increases, other than viral and alcoholic hepatitis. NAFLD includes a spectrum of liver pathology, from simple steatosis to nonalcoholic steatohepatitis (NASH), in which inflammatory changes and focal necrosis may progress to (1) liver fibrosis, (2) cirrhosis, and (3) hepatic failure. NAFLD is now considered to be an additional feature of the "metabolic syndrome" with serum amino-transferase elevation associated with (1) higher body mass index (BMI), (2) increased waist circumference, (3) elevated serum triglycerides, (4) elevated fasting insulin, and (5) lower HDL cholesterol—these features are characteristics of this syndrome.

Two- to fivefold increases of amino-transferases may occur in patients with primary or metastatic carcinoma of the liver, with AST usually being higher than ALT. Slight or moderate elevations of AST and ALT activities have been observed after administration of various medications, such as (1) nonsteroidal antiinflammatory drugs, (2) antibiotics, (3) antiepileptic drugs, (4) statins, or (5) opiates. Over-the-counter medications and herbal preparations are also implicated. In patients with increased amino-transferases, negative viral markers, and a negative history for drugs or alcohol ingestion, the diagnostic workup should include less common causes of chronic hepatic injury, such as (1) autoimmune hepatitis, (2) hemochromatosis, (3) Wilson disease, (4) primary biliary cirrhosis, (5) sclerosing cholangitis, (6) celiac disease, and (7) α_1 -antitrypsin deficiency.

As might be expected from the high AST concentration in muscle, AST activity also is increased in muscular dystrophy and dermatomyositis, although it is normal in muscular diseases of neurogenic origin. Finally, significant AST increases are noted in hemolytic disease.

Several studies have described AST linked to immunoglobulins, or macro-AST. Typical findings include a persistent increase in serum AST activity with normal ALT concentrations in an asymptomatic subject, with the absence of any demonstrable pathology in organs rich in AST. Increased AST activity might reflect decreased clearance of the abnormal complex from plasma. Macro-AST has no known clinical relevance. However, identification is important to avoid unnecessary diagnostic procedures in these subjects. The demonstration of macro-AST in serum is obtained by differential precipitation with polyethylene glycol (PEG) 6000 (see the Amylase section later in this chapter).

POINTS TO REMEMBER

- Routine testing of AST in addition to ALT is not recommended, because ALT is the more liver-specific enzyme and the incremental benefit of routine determination of AST, in addition to ALT, is very limited. Moreover, increases of ALT activity persist longer than AST.
- Laboratories should offer AST as a reflex test in samples with abnormal ALT results (e.g., higher than the upper reference limit [URL]), also reporting the AST-to-ALT ratio because it provides useful diagnostic and prognostic information.

from the skeleton. The respective contributions of these two forms to the total activity are age dependent. Minimal amounts of intestinal ALP may also be present, particularly in the sera of individuals of blood group B or O. Because intestinal ALP activity in serum may increase after a meal, ALP should be measured preferentially in fasting subjects.

Clinical Significance

Increases in serum ALP activity commonly originate from one or both of two sources: liver and bone. Consequently, serum ALP measurements are of interest in the investigation of hepatobiliary disease and bone disease associated with increased osteoblastic activity.

Hepatobiliary disease. The response of the liver to any form of biliary tree obstruction induces the synthesis of ALP by hepatocytes. The newly formed ectoenzyme is released from cell membrane by the action of bile salts and enters the circulation to increase the enzyme activity in serum. The increase tends to be more notable in extrahepatic obstruction (e.g., by stone, by cancer of the head of the pancreas) than in intrahepatic obstruction, and is greater the more complete the obstruction. Serum enzyme activities may reach 10 to 12 times the URL and usually return to baseline on surgical removal of the obstruction. A similar increase is seen in patients with advanced primary liver cancer or widespread secondary hepatic metastases. GGT activity is co-elevated with ALP in cases of obstructive intrahepatic or posthepatic biliary disease.

Liver diseases that principally affect parenchymal cells, such as infectious hepatitis, typically show only moderately (less than threefold) increased or even normal serum ALP activities. Increases may also be a consequence of a reaction to drug therapy, and ALT/ALP-based criteria to discriminate the type of liver injury in drug-induced hepatic toxicity have been recommended (Table 19.4). Intestinal ALP isoenzyme, an asialoglycoprotein normally cleared by the hepatic asialoglycoprotein receptors, is often elevated in patients with liver cirrhosis.

Bone disease. Bone ALP is produced by the osteoblast and has been demonstrated in matrix vesicles deposited as “buds” derived from the cell’s membrane. The enzyme

therefore is an excellent indicator of global bone formation activity. Genetic inability to produce tissue-nonspecific ALP, including bone isoform, a rare inherited disorder known as hypophosphatasia, results in severe bone disease and impaired bone growth.

Among the bone diseases, the highest concentrations of (bone) ALP are encountered in **Paget disease** (osteitis deformans) as a result of the action of osteoblastic cells as they try to rebuild bone that is being resorbed by uncontrolled activity of osteoclasts. Values from 10 to 25 times the URL are not unusual, and in broad terms, the increase reflects the extent of disease. In vitamin D deficiency (osteomalacia and rickets), enzyme concentrations two to four times the URL may be observed, and these fall to baseline on treatment. Hyperparathyroidism (primary and secondary) is associated with slight to moderate increases of bone ALP in serum, with the existence and degree of increase reflecting the presence and extent of skeletal involvement. Very high enzyme concentrations are present in patients with osteogenic bone cancer. Increased ALP indicates bone metastasis in 70% of prostate cancers, and its measurement has been included in the European Association of Urology guidelines for staging this neoplasia. Bone ALP can be slightly increased in osteoporosis, but individuals with osteoporosis are not clearly distinguished from age-matched controls. Transient increases of ALP may be found during the healing of bone fractures. Physiological bone growth increases bone ALP in serum, and this accounts for the fact that in the sera of growing children, the enzyme concentration is 1.5 to 7 times that in healthy adult serum, the maximum being reached earlier in girls than in boys.

Other conditions that increase alkaline phosphatase.

An increase of up to two to three times URL is observed in women in the third trimester of pregnancy, with the additional enzyme being of placental origin. Reports have described a benign familial increase in serum ALP activity caused by increased concentrations of intestinal ALP. Transient, benign increases in serum ALP may be observed in infants and children, with changes often more than 10 times the URL. These changes seem to reflect a reduction in the removal of ALP from blood caused by transient modifications of enzyme glycosylation.

ALP forms essentially identical to the normal placental or germ cell isoenzymes appear in the sera of some patients with malignant disease. This appears to result from de-repression of the corresponding genes. The presence of these isoenzymes can be readily detected in the serum by their increased stability at 65°C.

Methods of Analysis for Total Alkaline Phosphatase Activity and Isoenzyme Content

The most popular of the chromogenic substrates for ALP is 4-nitrophenyl phosphate (usually abbreviated 4-NPP, or PNPP from the older name, *p*-nitrophenyl phosphate). This ester is colorless, but the final product is yellow at the pH of the reaction:

TABLE 19.4 Enzyme-Based Criteria for Drug-Induced Liver Toxicity (Enzyme Values Expressed as Multiples of the Upper Reference Limit in Serum)

Injury Type	ALT	ALP	ALT/ALP Ratio
Hepatocellular	>2 URL	<URL	≥5
Cholestatic	<URL	>2 URL	≤2
Mixed	>2 URL	>2 URL	2–5

ALP, Alkaline phosphatase; ALT, alanine aminotransferase; URL, upper reference limit.

Data from the Council of International Organizations of Medical Sciences, 1990.

The enzymatic reaction is continuously monitored by observing the rate of formation of the 4-nitrophenoxide ions at 405 nm. This reaction forms the basis of current methods of ALP assay. The liberated phosphate group is transferred to water, and the rate of phosphatase action is enhanced if certain amino alcohols are used as phosphate-accepting buffers. Among these activators are compounds such as (1) AMP, (2) DEA, (3) TRIS, and (4) *N*-methyl-D-glucamine (MEG). The IFCC-recommended procedure uses 4-NPP as the substrate and AMP as the phosphate-acceptor buffer.

Serum or heparinized plasma, free of hemolysis, should be used. Complexing anticoagulants—such as citrate and EDTA—must be avoided because they bind cations, such as Mg^{2+} and Zn^{2+} , which are necessary cofactors for ALP activity. Freshly collected serum samples should be kept at room temperature and assayed as soon as possible, but preferably within 4 hours after collection. In sera stored at a refrigerated temperature, ALP activity increases slowly (2% per day). Frozen specimens should be thawed and kept at room temperature for 18 to 24 hours before measurement to achieve full enzyme reactivation.

Desirable analytical specifications for ALP determination are imprecision (CV) less than or equal to 3.0%, bias lower than $\pm 5.5\%$, and total error lower than $\pm 14\%$. As for other clinically important enzymes, the current emphasis is on the standardization and traceability of the commercial assays to the IFCC reference measurement system for ALP.

ALP activities in serum vary with age and, in a minor amount, with sex. Infants and peripubertal children show higher ALP activity (up to threefold) than healthy adults as a result of the leakage of bone ALP from osteoblasts during bone growth. However, activities in growing children are highly variable, and the decrease in ALP activity to typical adult ranges is known to differ from subject to subject, occurring on average 2 years earlier in females than in males. Using assays traceable to the IFCC reference procedure, the following ALP reference intervals have been established in adult individuals: 33 to 98 U/L for premenopausal women and 43 to 115 U/L for men.

Assays for ALP isoenzymes are needed when (1) the source of an increased ALP in serum is not obvious and should be clarified, (2) the main clinical question is concerned with detecting the presence of liver or bone involvement, or (3)

it is important to ascertain any modifications in the activity of osteoblasts to monitor disease activity and the effects of appropriate therapies in the case of metabolic bone disorders. Criteria that have been used to differentiate the isoenzymes and other multiple forms of ALP include (1) electrophoretic mobility, (2) stability to denaturation by heat or chemicals, (3) response to the presence of selected inhibitors, (4) affinity for specific lectins, and (5) immunochemical characteristics.

After electrophoresis, ALP zones are made visible by incubating the gel in a solution of buffered substrate. The liver ALP typically moves most rapidly toward the anode. Bone ALP, which typically gives a more diffuse zone than the liver form, has slightly reduced anodal mobility—although the two zones usually overlap to some extent. Whereas intestinal ALP migrates more slowly than the bone enzyme, the placental isoenzyme commonly appears as a discrete band overlying the diffuse bone fraction. An additional band, which is frequently present in the serum of patients with various hepatic diseases, contains a high molecular weight form of ALP that is strongly negatively charged. Therefore it moves slowly in or may even fail to enter polyacrylamide gel, but it migrates more anodally than the main liver zone on nonsieving media, such as cellulose acetate. This form corresponds to the main liver form attached to the membrane moiety. Complexes between ALP and immunoglobulins, or macro-ALP, occur occasionally in serum, giving rise to abnormally migrating bands in the γ -globulin zone; however, they do not provide specific clinical information in the present state of knowledge. A short (15 minutes at 37°C) sample pretreatment with neuraminidase to remove a portion of the terminal sialic acid residues can be used to improve the electrophoretic separation between bone and liver ALPs, exploiting differences in the carbohydrate portions of the two forms of ALP.

As an alternative to electrophoretic fractionation of ALP, measurement of γ -GGT, which is increased in liver disease but not in bone disease, may be a useful rapid tool to distinguish between the two diseases as the explanation for increased serum ALP.

Immunoassays for direct determination of bone ALP, which measure enzyme activity or mass concentration, are commercially available; cross-reactivity with the liver form by 6% to 20% has however been established, and their value has not been convincingly demonstrated, partly because measurements of total ALP provide the required clinical information in many situations.

γ -Glutamyltransferase

Peptidases are enzymes that catalyze the hydrolytic cleavage of peptides to form amino acids or smaller peptides. They constitute a broad group of enzymes of varied specificity, and some individual enzymes act as amino acid transferases and catalyze the transfer of amino acids from one peptide to another amino acid or peptide. **γ -Glutamyltransferase** (GGT) (EC 2.3.2.2; γ -glutamyl-peptide: amino acid γ -GGT) catalyzes the transfer of the γ -glutamyl group from peptides

and compounds to an acceptor. Substrates for GGT include (1) the γ -glutamyl acceptor, (2) an amino acid or peptide, or (3) even water, in which case simple hydrolysis takes place. The enzyme acts only on peptides or peptide-like compounds containing a terminal glutamate residue joined to the remainder of the compound through the terminal ($-\gamma$ -) carboxyl. Glycylglycine is five times more effective as an acceptor than is glycine or the tripeptide (gly-gly-gly). An example of a reaction catalyzed by the GGT is shown here:

Biochemistry

GGT is present (in decreasing order of abundance) in the (1) proximal renal tubules, (2) liver, (3) pancreas, and (4) intestine. The enzyme is present in cytoplasm (microsomes), but the larger fraction is located in the cell membrane and may transport amino acids and peptides into the cell across the cell membrane in the form of γ -glutamyl peptides. GGT is critical for the maintenance of adequate intracellular concentrations of reduced glutathione, a major antioxidant agent.

Clinical Significance

Even though renal tissue has the highest concentration of GGT, the enzyme present in serum appears to originate primarily from the hepatobiliary system. Thus GGT is considered a sensitive indicator of the presence of hepatobiliary disease, even if its usefulness is limited by lack of specificity. Like ALP, GGT activity is highest in cases of intrahepatic or posthepatic biliary obstruction, reaching activities some 5 to 30 times the URL. High increases of GGT are also observed in patients with a primary or

metastatic liver neoplasm. Moderate increases occur in infectious hepatitis. In acute and chronic pancreatitis and in some pancreatic malignancies (especially if associated with hepatobiliary obstruction), enzyme activity may be 5 to 15 times the URL.

Increased activities of GGT also are found in the sera of patients with alcoholic hepatitis and in the majority of sera from people who are heavy drinkers. GGT is also increased with increased body weight and obesity, and the effect of alcohol is more marked in these groups. Recent epidemiologic evidence has shown that serum GGT activity possesses an independent prognostic value for cardiovascular morbidity and mortality.

Increased concentrations of the enzyme are also found in the serum of subjects receiving anticonvulsant drugs such as phenytoin and phenobarbital. Such an increase in GGT activity in serum may reflect induction of new enzyme activity by the action of alcohol and drugs or their toxic effects on microsomal structures in liver cells.

Unlike ALP, serum GGT is not increased in conditions in which osteoblastic activity is increased, so the enzyme measurement can be useful in differentiating the source of ALP activity increase in serum, whether it is of bone or liver origin.

Methods of Analysis

Early GGT assays used L- γ -glutamyl-*p*-nitroanilide (GGPNA) as the substrate, with glycylglycine serving as the γ -glutamyl residue acceptor. The *p*-nitroaniline produced in the reaction is determined by its yellow color, which is monitored at 405 nm. However, GGPNA has limited solubility in the reaction mixture, and it is therefore difficult to obtain saturating substrate concentrations. To obviate this problem, derivatives of GGPNA, in which various groups have been introduced into the benzene ring to increase solubility in water, have been used. The most useful of these substrates is L- γ -glutamyl-3-carboxy-4-nitroanilide, which is readily soluble in water and is split by GGT at a rate comparable with that observed with GGPNA. In the IFCC reference measurement procedure for GGT, L- γ -glutamyl-3-carboxy-4-nitroanilide serves as the substrate, with glycylglycine serving as an acceptor. Buffering is provided by glycylglycine itself.

GGT activity is stable for at least 1 month at 4°C and for 1 year at -20°C. Nonhemolyzed serum is the preferred specimen, but EDTA plasma has also been used. Heparin may produce turbidity in the reaction mixture; citrate, oxalate, and fluoride depress GGT activity by 10% to 15%.

Desirable analytical specifications for GGT determination are imprecision (CV) $\leq 3.7\%$, bias lower than $\pm 11.8\%$, and total error lower than $\pm 22.2\%$.

In adults, the URL for GGT activity in serum is 40 U/L for females and 70 U/L for males, when measured with an assay traceable to the IFCC reference procedure. Reference limits are approximately twofold higher in people of African ancestry. In normal full-term neonates, GGT activity at birth is approximately six to seven times the adult reference interval. The activity then declines, reaching adult values by the age of 5 to 7 months.

5'-Nucleotidase

5'-Nucleotidase (NTP) (EC 3.1.3.5; 5'-ribonucleotide phosphohydrolase) is a phosphatase that acts only on nucleoside-5'-phosphates, such as adenosine-5'-phosphate (AMP) and adenylic acid, releasing inorganic phosphate.

NTP is a glycoprotein that is widely distributed throughout the tissues of the body and is principally localized in the cytoplasmic membrane of the cells in which it occurs. Despite its ubiquitous distribution, serum NTP activities appear to reflect hepatobiliary disease with considerable specificity. Particularly, NTP is increased in those hepatobiliary diseases in which there is an interference with the secretion of bile. This may be due to extrahepatic causes (a stone or tumor occluding the bile duct), or it may arise from intrahepatic conditions, such as cholestasis caused by malignant infiltration of the liver or biliary cirrhosis. When parenchymal cell damage is predominant, as in infectious hepatitis, serum NTP activity is only moderately increased.

The assay of NTP activity has been considered of value as an addition to measurement of ALP in patients with suspected hepatobiliary disease, and increased NTP activity is interpreted as evidence of a hepatic origin of increased ALP activity in serum. However, approximately half of individuals in whom liver ALP activity is increased in serum may simultaneously show a normal NTP. On the other hand, increased NTP in the serum of patients with normal liver ALP is very often associated with the presence of liver disease. Thus the frequent dissociation of the two enzyme activities supports the usefulness of determining both ALP and NTP to enhance diagnostic efficiency in patients with suspected liver disease. Different patterns of ALP and NTP are, however, not associated with specific hepatic conditions.

In a commercially available assay, serum NTP catalyzes the hydrolysis of inosine-5'-phosphate (IMP) to yield inosine, which is then converted to hypoxanthine by purine-nucleoside phosphorylase. Hypoxanthine is oxidized to urate with xanthine oxidase. Two moles of hydrogen peroxide are produced for each mole of hypoxanthine liberated and converted to uric acid. The formation rate of hydrogen peroxide is monitored at 510 nm by the oxidation of a chromogenic system. The effect of ALP on IMP is inhibited by β -glycerophosphate. Using this method, the reference interval for NTP activity at 37°C is from 3 to 9 U/L, with no sex-related differences.

NTP activity in serum or plasma heparin is stable for at least 4 days at 4°C and 4 months at -20°C. Desirable analytical specifications for NTP determination are imprecision (CV): $\leq 2.1\%$, bias lower than $\pm 2.9\%$, and total error lower than $\pm 8.3\%$.

PANCREATIC ENZYMES

The most commonly used serum biomarkers for investigation of pancreatic disease, and more specifically **acute pancreatitis**, are LIP and P-type amylase (see [Chapter 38](#)).

Lipase

Human pancreatic **lipase** (LIP) (EC 3.1.1.3; triacylglycerol acylhydrolase) is a single-chain glycoprotein with a molecular

weight of 48 kDa. For full catalytic activity and greatest specificity, the presence of bile salts and a cofactor called *colipase*, which is a small protein secreted by the pancreatic acinar cells, are required.

Biochemistry

Lipases are defined as enzymes that hydrolyze glycerol esters of long-chain fatty acids.

Only ester bonds at carbons 1 and 3 (α -positions) are attacked, and products of the reaction include 2 moles of fatty acids and 1 mole of 2-acylglycerol (β -monoglyceride) per mole of substrate. The latter is resistant to hydrolysis, but it can spontaneously isomerize to the α -form (3-acylglycerol). The isomerization permits the third fatty acid to be split off, but at a much slower rate.

LIP acts only when the substrate is present in an emulsified form at the interface between water and the substrate. The rate of LIP action depends on the surface area of the dispersed substrate. Bile acids ensure that the surface of the dispersed substrate remains free of other proteins, by lining the surface of the insoluble substrate and the aqueous medium.

Most LIP activity found in serum derives from the pancreatic acinar cells, but some is secreted by gastric and intestinal mucosa. LIP concentration in the pancreas is about 5000-fold greater than in other tissues, and the concentration gradient between the pancreas and serum is approximately 20,000-fold. LIP is a small enough molecule to be filtered through the glomerulus, but it is totally reabsorbed by the renal tubules, and it is not physiologically detected in urine.

Clinical Significance

LIP measurement in serum is the recommended laboratory test to diagnose acute pancreatitis. The clinical sensitivity is 80% to 100%, depending on the selected diagnostic cutoff, and the clinical specificity is 80% to 100%, depending on the mix of the patient population studied. After an attack of acute pancreatitis, serum LIP activity increases within 4 to 8 hours, peaks at about 24 hours, and decreases within 7 to 14 days ([Fig. 19.2](#)). Increases between 2 and 50 times the URL have been reported.

Fig 19.2 Time-dependent changes in serum amylase and lipase after acute pancreatitis.

Acute pancreatitis is sometimes difficult to diagnose because it must be differentiated from other acute intraabdominal disorders with similar clinical findings, such as (1) perforated gastric or duodenal ulcer, (2) intestinal obstruction, or (3) mesenteric vascular obstruction. A correct diagnosis of pancreatitis is vitally important, as the treatment for the other conditions mimicking pancreatitis typically involves surgery, while surgery is in general contraindicated in pancreatitis. In differential diagnosis, increase of serum LIP activity to greater than three times the URL, in the absence of renal failure, is a more specific diagnostic finding than increases in serum α -amylase activity. Furthermore, LIP concentrations remain

increased longer than those of α -amylase do, which is another advantage over α -amylase measurement in patients with delayed presentation (see Fig. 19.2). Therefore it is recommended that LIP should replace α -amylase as the initial diagnostic test for acute pancreatitis in the emergency department; obtaining both serum α -amylase and LIP is not warranted.

In patients with a reduced glomerular filtration rate, serum LIP activity is increased. Thus care should be exercised in the interpretation of increased serum LIP values in the presence of renal disease.

Methods of Analysis

Many LIP methods have been described; they have used both triglyceride and nontriglyceride substrates and (1) titrimetric, (2) turbidimetric, (3) spectrophotometric, (4) fluorometric, and (5) immunologic techniques. In general, long-chain triglyceride (and some diglyceride) substrates have demonstrated correlation of results with the clinical state that is superior to that seen with methods using other substrates. Spectrophotometric methods have the advantage of minimum sample volume requirements, good precision, wide dynamic range, and ease of automation. Numerous substrates and complex auxiliary and indicator systems have been used.

In the enzymatic reaction rate diglyceride assay for LIP, the following sequence of indicator and auxiliary enzymes is used:

TOOS is sodium *N*-ethyl-*N*-(2-hydroxyl-3-sulfo-3-propyl)-*m*-toluidine, and its oxidation produces an intensely colored dye detectable at 550 nm.

In another method, a synthetic substrate (1,2-*O*-dilauryl-rac-glycero-3-glutaric acid-[4-methyl-resorufin]-ester) consisting of two glycerol ether bonds and one ester bond is used.

LIP hydrolyzes the ester bond in an alkaline medium to an unstable dicarbonic acid ester that spontaneously hydrolyzes to yield glutaric acid and methylresorufin; this is a bluish-purple chromophore with peak absorption at 580 nm. The rate of methylresorufin formation is directly proportional to the LIP activity of the sample.

LIP activity in serum is stable at room temperature for 1 week; sera may be stored for 3 weeks in the refrigerator and for several years if frozen.

Biological variation data suggest that imprecision (CV) less than or equal to 3.9%, bias lower than $\pm 6.3\%$, and total error lower than $\pm 12.7\%$ for LIP measurements are required for clinical use.

Reference intervals for LIP activity are largely method dependent. For the enzymatic reaction rate diglyceride assay, the suggested URL is 45 U/L. The URL is 64 U/L for methylresorufin assay. There are no gender- or age-related differences.

Amylase

α -Amylases (AMY) (EC 3.2.1.1; 1,4- α -D-glucan glucanohydrolase) are enzymes that catalyze the hydrolysis of 1,4- α -glucosidic linkages in polysaccharides. Both straight-chain (linear) polyglucans (amylose) and branched polyglucans (amylopectin and glycogen) are hydrolyzed, but at different rates. AMYs do not attack the α -1,6-linkages at the branch points. AMYs are calcium metalloenzymes, with the calcium essential for functional integrity. However, full activity is displayed only in the presence of various anions, with chloride and bromide being the most effective activators.

Biochemistry

AMYs have molecular weights varying from 54 to 62 kDa. The enzyme is thus small enough to pass through the glomeruli of the kidneys, and AMY is the only plasma enzyme normally found in urine. AMYs are present in many organs and tissues. The greatest concentration is noted in the salivary glands, which secrete a potent AMY (S-type) to initiate hydrolysis of starches while the food is still in the mouth and esophagus. In the pancreas, the enzyme (P-type) is synthesized by acinar cells and then is secreted into the intestinal tract by way of the pancreatic duct system. AMY activity is also found in extracts from the (1) ovaries, (2) fallopian tubes, (3) lungs, and (4) adipose tissue. Some tumors of the lung and ovary may also contain considerable AMY activity (usually S-type) and produce hyperamylasemia. Cases of AMY-producing multiple myeloma have also been described.

The enzyme present in serum and urine is predominantly of pancreatic (P-AMY) and salivary gland (S-AMY) origin. These isoenzymes are products of two closely linked loci on chromosome 1. In healthy adults, P-AMY represents approximately 40% to 50% of total AMY activity in serum. AMY isoenzymes also undergo posttranslational modification of (1) deamidation, (2) glycosylation, and (3) deglycosylation, to form a number of isoforms.

Clinical Significance

Blood AMY activity is physiologically low and greatly increases in acute pancreatitis and salivary gland inflammation. In acute pancreatitis, a rise in serum AMY activity occurs within 5 to 8 hours of symptom onset; activities typically return to baseline by the third or fourth day (see Fig. 19.2). The specificity of AMY for the diagnosis of acute pancreatitis is, however, low (20% to 60%, depending on the mix of the patient population studied) because increased

TABLE 19.5 Causes of Hyperamylasemia

Pancreatic disease	Pancreatitis, any cause (P-AMY) ^a Pancreatic trauma (P-AMY)
Intraabdominal diseases other than pancreatitis	Biliary tract disease (P-AMY) Intestinal obstruction (P-AMY) Mesenteric infarction (P-AMY) Perforated peptic ulcer (P-AMY) Gastritis, duodenitis (P-AMY) Ruptured aortic aneurysm Acute appendicitis (perforated) Peritonitis Trauma
Genitourinary disease	Ectopic, ruptured tubal pregnancy (S-AMY) Salpingitis (S-AMY) Ovarian malignancy (S-AMY) Renal insufficiency (Mixed)
Miscellaneous	Salivary gland lesions (S-AMY) Acute alcoholic abuse (S-AMY) Diabetic ketoacidosis (S-AMY) Macroamylasemia (S-AMY or P-AMY) Septic shock (S-AMY) Cardiac surgery (S-AMY) Tumor (usually S-AMY) Drugs (usually S-AMY)

^aPredominant isoenzyme type is shown in parentheses.

Mixed, Either or both isoenzymes may be present; P-AMY, pancreatic; S-AMY, salivary.

values are also found in a number of acute intraabdominal disorders and in several extrapancreatic conditions (Table 19.5).

Lack of specificity of total AMY measurement has promoted the direct measurement of P-AMY instead of total enzyme activity for the differential diagnosis of patients with acute abdominal pain, making the measurement of total AMY obsolete. By applying the best decision limit (an activity equal to threefold the URL), the specificity of P-AMY for the diagnosis of acute pancreatitis is close to 90%. Sensitivity in late detection of this condition is also notably improved with P-AMY. P-AMY values remain increased in 80% of patients with uncomplicated pancreatitis 1 week after onset, when only 30% still show increased total AMY activity. This long-standing increase in P-AMY activity in serum also makes redundant the traditional measurement of total AMY in urine—a test performed to achieve better diagnostic sensitivity in the late phase of pancreatitis.

Various intraabdominal extrapancreatic events, such as acute **cholecystitis**, can lead to a significant increase in serum P-AMY activities. In renal insufficiency, serum P-AMY activity is increased in proportion to the extent of renal impairment.

In 1% of the population, macroamylases are present in sera and may cause hyperamylasemia; these are complexes of ordinary AMY (usually S-type) and IgG or IgA. These macroamylases cannot be filtered through the glomeruli of the kidneys because of their large size (>200 kDa molecular weight) and are thus retained in the plasma, where their presence may increase AMY activity some two- to eightfold above the URL, typically stable over time. No clinical symptoms are associated with this disorder.

POINTS TO REMEMBER

Pancreatic enzymes in acute pancreatitis:

- The diagnostic performance of pancreatic enzymes is greatly improved by restricting their use to a population with suspected disease.
- LIP measurement is superior to P-AMY in terms of diagnostic performance. Therefore it is recommended that LIP replaces P-AMY as an initial test for acute pancreatitis in emergency departments.
- Measuring both serum P-AMY and LIP is not warranted.
- The measurement of total AMY should be considered obsolete.

Methods of Analysis

The use of defined substrates in the AMY assay has improved the reaction stoichiometry and has led to more controlled and consistent hydrolysis conditions. Substrates used include (1) maltotetraose, (2) maltopentaose, and (3) 4-nitrophenyl (4-NP)-glycoside substrates prepared by bonding 4-NP to the reducing end of a defined oligosaccharide. If the oligosaccharide is maltoheptaose (G7), the substrate is then 4-NP-G7. AMY splits this substrate to produce free oligosaccharides (G5, G4, and G3) and 4-NP-G2, 4-NP-G3, and 4-NP-G4. Combined hydrolysis by AMY in the specimen and by the reagent α -glucosidase (EC 3.2.1.20; maltase) results in free NP production, which is detected by its absorbance at 405 nm. Problems arose with use of the 4-NP-glycoside assay with regard to the poor stability of the reconstituted assay mixture because of slow hydrolysis of the 4-NP-glycoside by α -glucosidase. This effect has been reduced by covalently linking a “blocking” group (i.e., a 4,6-ethylidene group; ethylidene-protected substrate [EPS]) to the nonreducing end of the molecule. The blocked substrate also shows a more advantageous hydrolysis pattern, thus increasing the liberation of 4-NP. As a result, cleavage of

one α -glucosidic linkage by AMY results in the release of one molecule of 4-NP.

Only methods based on selective S-AMY inhibition by monoclonal antibodies have shown sufficient (1) precision, (2) reliability, (3) practicability, and (4) analytical speed to be clinically useful for P-AMY determination. After the S-AMY activity is inhibited by the addition of antibodies, uninhibited P-AMY activity is measured using EPS-4-NP-G7 as a substrate. This assay is available in full automation today on clinical chemistry platforms with reagent costs similar to total AMY, which permits laboratories to abandon the latter.

Falsely increased P-AMY results have been reported in subjects with macroamylasemia, in whom immunoglobulin complexed to AMY forms; these complexes diminish or void the ability of monoclonal antibodies, included in the test, to efficiently inhibit S-AMY. In this condition, precipitation of the macrocomplex by a PEG 6000 solution (240 g/L) presents an easy and effective approach to confirm the suspicion of macroamylasemia. Residual P-AMY activity of less than 30% in the supernatant is indicative of macroamylasemia (Fig. 19.3).

Except for heparin, all common anticoagulants inhibit AMY activity because they chelate calcium. Therefore P-AMY assay should be performed only on serum or heparinized

Fig 19.3 Demonstration of macroamylasemia by polyethylene glycol (PEG) 6000 solution. P-AMY, Pancreatic amylase.

plasma. AMY is quite stable; activity is fully retained during storage for 4 days at room temperature, for 2 weeks at 4°C, and for 1 year at -25°C.

Biological variation data suggest that P-AMY measurements require an imprecision (CV) $\leq 3.2\%$, maximum bias of $\pm 6.4\%$, and a total error lower than $\pm 11.6\%$ for good quality.

Using the immunoinhibition method, the reference interval for P-AMY activity in sera from adults is 13 to 53 U/L. Serum P-AMY activity is not demonstrable in most children younger than 6 months, but activity rises slowly thereafter to reach adult concentrations at 5 years of age, reflecting the postnatal development of exocrine pancreatic function. Therefore the use of this enzyme for diagnostic purposes in young children should be avoided.

OTHER CLINICALLY IMPORTANT ENZYMES

Lactate Dehydrogenase

LDH (EC 1.1.1.27; l-lactate: NAD⁺ oxidoreductase) catalyzes the oxidation of l-lactate to pyruvate with the mediation of NAD⁺ as a hydrogen acceptor.

As indicated, the reaction is reversible, and the reaction equilibrium strongly favors the reduction of pyruvate to lactate (P $\rightarrow$ L)—the “reverse reaction.” Both pyruvate and lactate in excess inhibit enzyme activity, although the effect of pyruvate is greater. EDTA inhibits the enzyme perhaps by binding zinc ions, postulated as LDH activators.

Biochemistry

LDH has a molecular weight of 134 kDa and is composed of four peptide chains of two types, M (or A) and H (or B), each under separate genetic control. The subunit compositions of the five isoenzymes are LDH-1 (HHHH; H₄), LDH-2 (HHHM; H₃M), LDH-3 (HHMM; H₂M₂), LDH-4 (HMMM; HM₃), and LDH-5 (MMMM; M₄).

LD activity is present in many cells of the body and is invariably found only in the cytoplasm of the cell. Different tissues show different isoenzyme composition. In the heart, kidneys, and erythrocytes, isoenzymes LDH-1 and LDH-2 predominate, while LDH-4 and LDH-5 isoenzymes account for the enzyme activity in the liver and skeletal muscle.

Clinical Significance

Because of its wide tissue distribution, serum LDH increases occur in a variety of clinical conditions, including (1) myocardial infarction, (2) hepatitis, (3) hemolysis, and (4) disorders of the lung and muscle. Serum LDH measurement is, however, relevant only in hematology and oncology.

Hemolytic anemias significantly increase LDH concentrations in serum. Marked increases of LDH activity—up to

50 times the URL—have been observed in the megaloblastic anemias, usually resulting from the deficiency of folate or vitamin B₁₂. These increases rapidly return to normal after appropriate treatment. For monitoring purposes, LDH is relevant in predicting disease activity in leukemia, and the survival rate (probability of survival) and duration in Hodgkin disease and non-Hodgkin lymphoma.

Patients with malignant disease often show increased LDH activity in serum; up to 70% of patients with liver metastases, and 20% to 60% of patients with other nonhepatic metastases (e.g., lymph nodes) have increased LDH activity. Notably elevated LDH-1 is observed in germ cell tumors ($\approx 60\%$ of cases) such as seminoma of the testis and dysgerminoma of the ovary. LDH appears to be a useful predictor of outcome in patients with testicular tumor, melanoma, and small cell lung cancer.

Increases of LDH activity are observed in liver disease, but their clinical use appears limited and does not appear to add significantly to the aminotransferase activity investigation. LDH measured in pleural fluid (in combination with serum LDH) aids in distinguishing exudative from transudative effusions. Macro-LDH, which usually occurs as a result of the formation of an autoantibody-enzyme complex leading to a persistent increase in the amount of circulating enzyme, has been estimated to occur in fewer than 1 in 10,000 people.

Methods of Analysis

Methods for quantitation of LDH activity use kinetic spectrophotometry to measure the interconversion of the coenzyme NAD⁺ and NADH at 340 nm. Procedures employing the L $\rightarrow$ P reaction are recommended because there is less dependence on the NAD⁺ and lactate concentrations and less contamination of NAD⁺ with inhibiting products.

Serum is the preferred specimen for measuring LDH activity. Plasma samples may be contaminated with platelets, which contain high concentrations of LDH. Serum should be separated from the clot as soon as possible after the specimen has been obtained. Hemolyzed serum must not be used because erythrocytes contain 4000 times more LDH activity than the serum. LDH-4 and LDH-5 isoenzymes are very sensitive to cold. Thus serum specimens should be stored at room temperature, at which no loss of activity occurs for at least 3 days.

The specifications for desirable performance of LDH assays, derived from biological variation of the enzyme, are as follows: imprecision (CV) $\leq 2.6\%$; bias lower than $\pm 3.4\%$; and total error lower than $\pm 7.7\%$.

The reference interval for LDH activity in adults, applicable for assays traceable to the IFCC reference procedure, was found to be 125 to 220 U/L. LDH reference intervals are higher in children, with a gradual decrease noted over the whole childhood period.

Electrophoretic separation is the only procedure commercially available to demonstrate LDH isoenzymes. However, considering the described limited clinical use of the enzyme to hematology and oncology, LDH isoenzyme measurement is usually not routinely done.

Cholinesterase

Two related enzymes have the ability to hydrolyze acetylcholine. One is acetylcholinesterase (EC 3.1.1.7; acetylcholine acetylhydrolase), which is called *true cholinesterase* or *choline esterase I*. True **cholinesterase** is found in (1) erythrocytes, (2) the lungs and spleen, (3) nerve endings, and (4) the gray matter of the brain. It is responsible for the prompt hydrolysis of acetylcholine released at the nerve endings to mediate transmission of the neural impulse across the synapse. The second cholinesterase is acylcholine acylhydrolase (EC 3.1.1.8; acylcholine acylhydrolase), also called *pseudocholinesterase*, *serum cholinesterase* (CHE), *butyrylcholinesterase*, or *choline esterase II*. CHE is found in the (1) liver, (2) pancreas, (3) heart, (4) white matter of the brain, and (5) serum. Its exact biological role is unknown.

The type of reaction catalyzed by both cholinesterases is shown:

Biochemistry

Of clinical interest are the atypical (genetic) variants of the CHE, characterized by diminished activity against acetylcholine and other substrates, which are found in the sera of a small fraction of apparently healthy people. The gene controlling the synthesis of CHE can exist in many allelic forms. Four of the most common forms are designated as E^u , E^a , E^f , and E^s . These four allelic genes can be combined to form one normal and nine abnormal genotypes. The normal, most common genotype is designated as E^uE^u , or UU (u for *usual*). The gene E^a is referred to as the *atypical* gene; the sera of people homozygous for this gene ($E^aE^a = AA$) are only weakly active toward most substrates for CHE and demonstrate increased resistance to inhibition of enzyme activity by dibucaine. The E^f gene (f for *fluoride resistant*) gives rise to a weakly active enzyme but with increased resistance to fluoride inhibition. The E^s gene (s for *silent*) is associated with the absence of enzyme or the presence of a protein with minimal or no catalytic activity. Homozygous forms, AA and FF , are found in 0.3% to 0.5% of the white population; their incidence among blacks is even lower.

Clinical Significance

Measurements of CHE activity in serum are used (1) as a test of liver function, (2) as an indicator of possible insecticide poisoning, and (3) for the detection of patients with atypical forms of the enzyme who are at risk for prolonged responses to certain muscle relaxants used in surgical procedures.

In the absence of genetic causes or known inhibitors, any decrease in CHE activity reflects impaired synthesis of the enzyme by the liver. Among the organic phosphorous compounds that inhibit CHE activity are many insecticides, such as (1) parathion, (2) sarin, and (3) tetraethyl pyrophosphate. Workers in agriculture and in organic chemical industries may be subject to poisoning by inhalation of these materials or by direct contact with them.

Succinylcholine (suxamethonium) and mivacurium, muscle relaxant drugs used in surgical procedures to aid in endotracheal intubation, are hydrolyzed by CHE, and their pharmacologic effect normally persists only long enough to meet the needs of the surgical procedure. In individuals with low enzyme activities or in those with a weakly active variant, destruction of the drug will not occur rapidly enough, and the subject may enter a period of prolonged paralysis of the respiratory muscles (apnea) requiring mechanical ventilation until the drug effects gradually wear off. Measurements of total CHE activity and determination of “dibucaine number” and “fluoride number” are needed to fully characterize CHE variants. The latter values indicate the percentage inhibition of enzyme activity in the presence of standard concentrations of dibucaine or fluoride. Mutation genotyping may confirm CHE gene abnormalities.

Methods of Analysis

Many of the contemporary methods use acylthiocholine esters as substrates. The iodide salts of (1) acetylthiocholine, (2) propionylthiocholine, (3) butyrylthiocholine, (4) benzoylthiocholine, and (5) succinylthiocholine all have been used. After the substrate hydrolysis, the thiocholine formed can be measured by reaction with chromogenic disulfide agents, such as 5,5'-dithio-bis(2-nitrobenzoate) (DTNB). The reaction of the thiocholine product with colorless DTNB forms colored 5-mercapto-2-nitro-benzoic acid, which is measured spectrophotometrically at 410 nm. Measuring CHE activity using succinylthiocholine is the method of choice to diagnose succinylcholine sensitivity, purely based on the enzyme activity recorded in serum. At present, however, most automated instruments prefer the use of butyrylthiocholine as substrate for determining the CHE activity. Based on differences in sensitivity to inhibition by the local anesthetic dibucaine, a simple test was developed to classify the type of CHE as (1) usual, (2) intermediate, or (3) atypical (“dibucaine number”). Particularly, the usual CHE is inhibited by 80%, but atypical CHE is inhibited by only 20%. Subjects heterozygous for the normal and the atypical gene show about 60% inhibition of CHE. Recently, molecular methods to detect CHE variants have been developed and are being used increasingly in clinical laboratories.

Serum is the sample of choice. Enzyme activity in serum is stable for several weeks if the specimen is stored under refrigeration and for several years if stored at -20°C .

Desirable analytical specifications for CHE determination are imprecision (CV) less than or equal to 3.1%, bias lower than $\pm 4.8\%$, and total error lower than $\pm 9.8\%$.

Using the succinylthiocholine/DTNB method, the reference interval for healthy adults with the usual CHE genotype was estimated to be 33 to 76 U/L for women and 40 to 78 U/L for men, respectively. The median activity in individuals with heterozygous genotype was 22 U/L (range, 5 to 35 U/L), and for atypical homozygotes 1.5 U/L (range, 1 to 4 U/L). The significant CHE decrease ($\approx 30\%$) during pregnancy and early puerperium is explained by hemodilution.

Acid Phosphatase (Tartrate-Resistant 5b Isoform)

Under the name of **acid phosphatase** (ACP; EC 3.1.3.2; orthophosphoric-monoester phosphohydrolase [acid optimum]) are included all phosphatases with optimal activity below a pH of 7.0. ACP is present in lysosomes, which are organelles present in all cells with the possible exception of erythrocytes. Extralysosomal ACPs are also present in many cells. The greatest concentrations of ACP activity occur in the (1) prostate, (2) bone (osteoclasts), (3) spleen, (4) platelets, and (5) erythrocytes. The lysosomal and prostatic enzymes are strongly inhibited by dextrorotatory tartrate ions, but the erythrocyte and bone isoenzymes are not. Most of the physiologically low ACP activity of (unhemolyzed) serum is of a tartrate-resistant type (TR-ACP) and probably originates mainly in osteoclasts. Activities of this fraction are increased physiologically in growing children and pathologically in conditions of increased osteolysis and bone remodeling.

At least four ACP-determining genes have been identified and mapped. The erythrocyte ACP gene is located on chromosome 2, and a further gene on chromosome 19 encodes the TR-ACP expressed in osteoclasts and other

tissue macrophages, such as alveolar macrophages and Kupffer cells (type 5 ACP). Isoenzyme 5 consists of two structurally related isoforms that differ by their carbohydrate content: TR-ACP 5a, which derives mainly from macrophages and dendritic cells, and type 5b, a more specific marker of osteoclastic activity. Genes encoding the tartrate-inhibited lysosomal and prostatic ACPs, mapped to chromosomes 11 and 13, respectively, exhibit considerable homology.

Serum TR-ACP is a potentially useful marker of conditions with a marked osteolytic component. Unlike blood concentrations of other markers of bone resorption (e.g., C-telopeptide of type I collagen), TR-ACP is not affected by renal dysfunction. However, TR-ACP appears to show relatively small dynamic changes in comparison with markers of bone resorption related to type I collagen metabolism. This may be attributable to the fact that the enzyme is released into the sealed osteoclast microenvironment, rather than directly into the circulation.

Immunoassays for serum TR-ACP have been developed that preferentially detect isoform 5b and are now commercially available. There is, however, the reality that both immunoassays are not entirely bone specific.

Serum should be immediately separated from erythrocytes and stabilized by the addition of 50 μL of acetic acid (5 mol/L) per milliliter of serum to lower the pH to 5.4, at which the enzyme is stable. Under these conditions, TR-ACP activity is maintained at room temperature for several hours, for up to 1 week if the serum is refrigerated, and for 4 months if stored at -20°C . Hemolyzed serum specimens are contaminated with the erythrocyte tartrate-resistant isoenzyme and should be rejected.

REVIEW QUESTIONS

1. The enzyme that demonstrates highest serum activity in Paget disease (osteitis deformans) and is also elevated in hepatobiliary disease is:
 - a. alkaline phosphatase (ALP).
 - b. creatine kinase (CK).
 - c. amylase (AMY).
 - d. α -glutamyltransferase (GGT).
2. Activity of which of the following isoenzymes of lactate dehydrogenase (LDH) is highest in the serum of individuals with seminoma of the testis?
 - a. LDH-1
 - b. LDH-2
 - c. LDH-4
 - d. LDH-5
3. The serum enzyme that demonstrates an increase in activity 4 to 8 hours after an attack of acute pancreatitis, peaks at 24 hours, and then returns to normal within a week is:
 - a. AMY.
 - b. lipase (LPS).
 - c. ALP.
 - d. serum cholinesterase (CHE).
4. Which of the following enzymes catalyzes the reaction of glutamate and pyruvate to form 2-oxoglutarate and an amino acid?
 - a. ALP
 - b. Aspartate aminotransferase (AST)
 - c. Alanine aminotransferase (ALT)
 - d. CK
5. In the laboratory measurement of ALP, a chromogenic assay forms the basis of almost all current methods used for ALP analysis. The substrate in this assay is:
 - a. acid phosphatase.
 - b. 4-nitrophenyl phosphate.
 - c. *p*-nitroaniline.
 - d. succinylthiocholine.
6. Measurement of decreased activity of which of the following enzymes is used to determine possible insecticide poisoning?
 - a. CK
 - b. ALP
 - c. ALT
 - d. CHE

7. Children have higher ALP activity than healthy adults because:
 - a. ALP leaks from osteoblasts during normal bone growth.
 - b. developing hepatocytes produce excess ALP during normal growth.
 - c. striated muscle contains the greatest activity of ALP, and children are more energetic than adults with concomitant release of excess ALP from muscle.
 - d. the presence of ALP in the pancreas is elevated during childhood.
8. The isoenzyme of amylase that is synthesized by acinar cells of the pancreas and that remains elevated in most individuals for at least 1 week after the onset of pancreatitis is:
 - a. S-AMY.
 - b. macro-AMY.
 - c. P-AMY.
 - d. S-AMY + P-AMY.
9. Which of the following enzymes demonstrates an increase in activity with progressive Duchenne muscular dystrophy, followed by a decrease as muscle mass decreases?
 - a. ALP
 - b. ALT
 - c. CHE
 - d. CK
10. The oxidoreductase that is increased significantly during megaloblastic anemia is:
 - a. LDH.
 - b. CK.
 - c. ALP.
 - d. acid phosphatase.

Tumor Markers

Catharine Sturgeon

OBJECTIVES

1. List the requirements of the “ideal” tumor marker.
2. Describe how to validate a “new” tumor marker.
3. Describe the major applications of tumor markers, providing specific examples as recommended in clinical guidelines.
4. Outline requirements of an optimal tumor marker service from test request to laboratory report.
5. Describe pitfalls and caveats in the use and interpretation of tumor markers.

KEYWORDS AND DEFINITIONS

Cancer Heterogeneous but related diseases characterized by uncontrolled division of cells.

Diagnostic accuracy The ability of a test to identify correctly patients who have malignancy.

Heterophilic antibodies Antibodies that may react with immunoassay reagents, yielding inappropriately high or low results.

High-dose “hooking” Interference leading to inappropriately low results for specimens of high analyte concentrations.

Prognosis Prediction of the likely outcome of disease with respect to risk of relapse or progression.

Screening Detection of unsuspected disease in asymptomatic subjects.

Serial monitoring Posttreatment tumor marker measurement enabling early detection of disease progression.

Therapy prediction Identification of patients likely to benefit from a particular treatment.

Tumor marker A substance present in abnormally high concentrations in body fluids or tissue from cancer patients.

Tumor markers are substances that may be present in abnormally high concentrations in body fluids or tissue from patients with cancer. Tumor markers can aid cancer management in a number of ways, including screening, diagnosis, prognostic assessment, **therapy prediction**, and/or post-treatment monitoring (Table 20.1). Reflecting the heterogeneous nature of cancer, tumor markers encompass a variety of molecular species. Many tumor markers are produced by a variety of different tumors, and few tumor markers are organ-specific or specific for a single type of malignancy.

Tumor markers range from simple molecules (e.g., catecholamines) through relatively well-characterized proteins (e.g., hormones) to much more heterogeneous glycoproteins and mucins (e.g., cancer antigen 125 [CA 125]), which may be defined by the antibodies used to measure them. Several important tumor markers (e.g., α -fetoprotein [AFP], carcinoembryonic antigen [CEA], and human chorionic gonadotropin [hCG]) are oncofetal antigens, which are present in the fetus in normal pregnancy but are expressed at high concentrations in tissue or body fluids of adults with some cancers. Tumor markers are present in cells, tissues, or body fluids and can be measured either

qualitatively or quantitatively using chemical, immunologic, or molecular biologic methods. Although their structures and properties vary widely, the broad principles underpinning their evidence-based clinical use are common to all tumor markers.

This chapter provides a brief overview of cancer and tumor marker development followed by a comprehensive review of these principles. Clinically relevant tumor markers for a number of malignancies are then discussed in detail, considering current practice and future requirements.

CANCER—AN OVERVIEW

Cancer is the name given to a collection of heterogeneous but related diseases that can start in most parts of the body and are characterized by uncontrolled division of cells, which ultimately may spread into surrounding tissues. Causative factors include exposure to carcinogens, which may be physical (e.g., radiation), chemical (e.g., polycyclic hydrocarbons), or biological (e.g., viral). Excess weight, physical inactivity, and poor nutrition may also contribute to the development of some cancers.

TABLE 20.1 Current Clinical Applications of Tumor Markers

Clinical Application	Requirements	Examples
Screening for cancer	An acceptable test for a disease that poses an important health problem, for which the natural history is well understood, the test identifies treatable early stage and early intervention with effective treatment improves outcome. High clinical sensitivity (few false-negatives) and specificity (few false-positives) are essential prerequisites as the population screened is asymptomatic.	<i>Population screening:</i> Fecal occult blood testing for colorectal cancer. <i>Screening of high-risk groups:</i> Serum hCG testing for choriocarcinoma in women who have had a molar pregnancy.
Diagnosing cancer	High clinical sensitivity and specificity as for screening. Most serum tumor markers are not cancer specific and/or organ specific and are raised in different cancers and/or in nonmalignant disease, severely limiting their use in diagnosis.	<i>As a diagnostic aid in high-risk groups:</i> Serum AFP testing as an adjunct to ultrasound for hepatocellular carcinoma (HCC) in patients with cirrhosis who are at high risk of developing HCC. <i>Differential diagnosis:</i> CA 125 contributes (with menopausal status and ultrasound findings) to calculation of the risk of malignancy index, which is used to differentiate patients with benign and malignant pelvic masses.
Assessing prognosis	A test that can provide a probability estimate of outcome (risk of relapse or disease progression) and/or differentiate indolent from aggressive disease for a heterogeneous population of patients, thereby influencing treatment decisions.	Serum AFP, hCG, and lactate dehydrogenase measurements are mandatory for determining prognosis and selection of chemotherapy in patients with metastatic nonseminomatous germ cell tumors. Microsatellite instability (MSI) occurs when germline alleles of microsatellites (short stretches of DNA that are repeated at multiple locations throughout the genome) lose or gain a repeat unit due to failure of mismatch repair. Presence of MSI is associated with good prognosis in colorectal cancer patients, especially in stage II or III disease, and their presence, associated with other established prognostic factors, may obviate the need for adjuvant chemotherapy in patients with stage II disease. Gene expression profiles such as the Oncotype Dx test, which measures expression of 21 genes in breast tumor tissue, enable calculation of a recurrence score that predicts the risk of distant disease at 10 years in a specific subset of breast cancer patients.
Prediction of treatment response	A test that can identify whether or not a potential treatment is likely to be effective and of benefit to the patient.	Measurement of estrogen receptors is mandatory for all newly diagnosed invasive breast cancer to predict response to treatment with antiestrogen therapy (e.g., aromatase inhibitors and tamoxifen). The additional measurement of progesterone receptors can improve the accuracy of prediction. Measurement of human epidermal growth factor receptor 2 (HER2) is essential to identify patients with HER2-positive breast cancer who are likely to benefit from treatment with anti-HER2 monoclonal antibody therapy.
Monitoring response during and/or shortly after treatment	A test that assesses whether the tumor is responding to treatment, enabling withdrawal and/or change of ineffective treatment.	In patients receiving treatment for ovarian cancer a reduction of at least 50% in CA 125 concentrations from a pretreatment sample has been defined as a response provided it is confirmed and maintained for at least 28 days and the pretreatment CA 125 concentration was greater than twice the upper limit of the reference interval and measured within 2 weeks of the start of chemotherapy. Biologic response to systemic chemotherapy, as assessed by serial measurement of serum CEA and CA 19-9 in patients receiving chemotherapy for colorectal cancer with liver metastases, agrees with response as assessed by radiology in >94% and 91% of patients, respectively, suggesting that this could decrease the need for imaging studies, such as CT, which require exposure of patients to significant doses of radiation.

TABLE 20.1 Current Clinical Applications of Tumor Markers—cont'd

Clinical Application	Requirements	Examples
Monitoring disease post treatment to detect progression	A test that reliably indicates earlier than clinical symptoms whether disease is progressing in patients with no evidence of disease post therapy and/or in patients with detectable disease. Whether this information is helpful crucially depends on whether alternative therapies are available.	Inclusion of CEA measurements in intensive follow-up strategies for patients with nonmetastatic colorectal cancer following curative surgery have been shown to improve overall survival. Such follow-up is also associated with earlier detection of recurrence.

AFP, α -Fetoprotein; *CA 125*, cancer antigen 125; *CA 19-9*, cancer antigen 19-9; *CEA*, carcinoembryonic antigen; *CT*, computerized tomography; *hCG*, Human chorionic gonadotropin.

Genetic predisposition to some cancers is increasingly identifiable due to advances in molecular techniques. Simple genetic analysis of mutations within cancerous cells may be too simplistic to explain a complex process, but increased understanding of such interactions is already leading to more finely targeted therapies.

Cancer remains a leading cause of death in the United States, second only to heart disease, although death rates have decreased significantly over the past three decades. Early detection and more effective treatment combined with prevention (e.g., decreased smoking, improved diet) may further reduce the cancer mortality rate. However, identification of smaller more indolent cancers with newer techniques and screening programs may also contribute to the perceived increase in survival.

Reflecting advances in treatment over recent decades, many patients survive for much longer than previously. Although surgical removal of a primary tumor is the only curative therapy for almost all cancers, new chemotherapeutic and biologic therapies that prevent progression are increasingly available. Some relatively indolent cancers are now almost regarded as chronic diseases like diabetes, to be controlled rather than cured. Breast and prostate cancers are among the best examples. However, for these and other cancers, distinguishing cancers that are likely to progress rapidly from those that are slow growing or indolent is critical and remains a challenge.

Early detection of malignancy optimizes any opportunities for curative surgery for some in situ cancers. Unfortunately, most cancers do not produce symptoms until tumors are too large to be removed surgically or until cancerous cells have spread to other tissue either by invading local lymph nodes or by distant spread (metastasis) to other organs. Systemic treatments (chemotherapy, endocrine therapy, or immunotherapy) are then usually the only options but are not curative. Any residual viable cancerous cells remaining after treatment may proliferate, develop resistance to further therapy, and ultimately cause the death of the patient.

HISTORICAL BACKGROUND

The introduction of new tumor markers has mirrored developments in analytical techniques and more recently the availability of new therapies, many of which are effective only in subsets of cancer patients.

The first tumor marker to be used clinically was Bence Jones protein, identified in 1847, and it is still the basis of many diagnoses of multiple myeloma. In the first half of the 20th century the presence or absence of other hormones, enzymes and isoenzymes, and blood group antigens was recognized to be associated with malignancy, but it was not until development of the technique of radioimmunoassay (RIA) in the 1960s that these observations could be translated into routine clinical practice (refer to [Chapter 15](#)). Monoclonal antibody technology subsequently enabled the development of two-site immunometric assays of complex cancer-associated mucins identified primarily by their reactivity with given monoclonal antibody pairs (e.g., the cancer-associated antigens CA 125 and CA 15-3). As automated methods became available, many more laboratories added tumor markers to their test repertoires.

Advances in molecular genetics, including the study of oncogenes, suppressor genes, and genes involved in DNA repair, have led to rapid understanding and use of tumor markers at both the molecular and cellular levels, particularly in high-risk individuals. Estrogen, progesterone, and epidermal growth factor receptor (EGFR) measurements are now routinely performed for breast cancer patients to inform treatment decisions, and measurement of the breast cancer susceptibility genes *BRCA1* and *BRCA2* provides additional prognostic information.

Mass spectrometry is also increasingly used both as a discovery and a diagnostic tool, albeit with limited success thus far in translating new tumor marker tests into clinical practice. These developments require sophisticated bioinformatics support, which encourages multiparametric analysis for cancer diagnosis, prognosis, and therapy prediction.

GENERAL PRINCIPLES GUIDING THE USE OF ALL TUMOR MARKERS

Tumor markers can help make or confirm a cancer diagnosis, monitor treatment effectiveness and the course of disease, estimate prognosis, and/or predict whether a specific therapy is likely to be successful ([Table 20.1](#)). Their measurement should permit more efficient application of therapies, by ensuring that these are applied only to those patients most likely to benefit and reducing exposure to unnecessary toxicity for those patients unlikely to benefit. Tumor markers

TABLE 20.2 Properties and Applications of Commonly Requested Serum Tumor Markers

Tumor Marker	Biochemical Properties	Molecular Weight	Main Clinical Applications
Alkaline phosphatase	Phosphohydrolase	Variable	Raised activities associated with presence of liver and/or bone metastases
α -Fetoprotein	Glycoprotein, 4% carbohydrate; considerable homology with albumin	~70 kDa	Diagnosis and monitoring of primary hepatocellular carcinoma, hepatoblastoma, and GCTs. Prognosis of GCT
Cancer antigen 125	Mucin identified by monoclonal antibodies OC125 and M11. Developed from serous cystadenocarcinoma cell line	~200 kDa	Monitoring ovarian carcinoma. Measurement required for determination of the risk of malignancy index for ovarian carcinoma
CEA	Family of glycoproteins, 45%–60% carbohydrate	~180 kDa	Monitoring colorectal adenocarcinomas
ConfirmMDx	A multiplex epigenetic assay	Not applicable	Reducing unnecessary repeat prostatic biopsies in men who have had at least one negative biopsy
Human chorionic gonadotrophin	Glycoprotein hormone consisting of two noncovalently bound subunits (α and β). α -Subunit similar to LH, FSH and TSH. β -Subunit considerable homology with LH	~36 kDa	Diagnosis, prognosis, and monitoring of GCTs and gestational trophoblastic neoplasia
Lactate dehydrogenase	Enzyme of the glycolytic pathway	Variable	Diagnosis, prognosis, and monitoring of GCTs. Used to monitor a wide range of malignancies including hematologic malignancies
Paraproteins	Monoclonal immunoglobulins	Variable	See Chapter 18
Prolactin	Pituitary hormone	~22 kDa but high molecular forms also exist	See Chapter 40
PSA	Glycoprotein, member of the kallikrein family with serine protease activity. Circulates as free enzyme or complexed to α_1 -antichymotrypsin (measurable) or α_2 -macroglobulin (not detected by most immunoassays)	~30 kDa (free enzyme)	Diagnosis, risk assessment and monitoring of prostate carcinoma. Lower concentrations of free PSA relative to complexed PSA (i.e., free:total ratio) found in prostatic cancer as compared with benign prostatic hypertrophy

CEA; Carcinoembryonic antigen; GCT, germ cell tumor; PSA, prostate-specific antigen.

should be measured only after considering whether the result is likely to provide information that may improve the outcome for the individual patient or as part of a clinical trial.

An evidence-based approach to clinical decision making is therefore essential, and careful consideration must be given to whether an individual tumor marker can fulfill requirements in selected clinical circumstances. Guidelines published by the National Comprehensive Cancer Network (NCCN) in the United States include patient pathways that clearly indicate which tumor markers should be measured and when. Complementing these clinically oriented guidelines, those published by the National Academy of Clinical Biochemistry (NACB) focus on the use of tumor markers, considering in detail requirements for their appropriate use in all phases of both the patient pathway and laboratory provision, helpfully comparing recommendations made with those of other groups. These are summarized later in this chapter.

Well-established and commonly requested serum tumor markers whose measurements are generally available in most large clinical laboratories are described in [Table 20.2](#). Some less commonly requested serum tumor markers with an

established clinical role are shown in [Table 20.3](#). [Table 20.4](#) lists some tissue markers essential to informed selection of endocrine and immunotherapy in individual patients.

The broad principles guiding the validation of any new tumor marker and its subsequent introduction into routine clinical practice are essentially similar and are considered in detail in the following sections. Early critical aspects include rigorous validation of analytical performance and clinical utility and demonstration of clinical value. Objective assessment of the potential clinical value of a proposed new tumor marker together with an estimate of the magnitude of its benefit, including effect on patient outcome, is now a prerequisite for introducing a new test into routine practice. Three key issues in tumor marker evaluation are clinical utility, magnitude of effect, and reliability. Only when these have been established and regulatory requirements fulfilled should the tumor marker be adopted into clinical practice. It is then essential to ensure that the new test is requested appropriately, that those requesting the test are aware of any preanalytical requirements, that these are met in routine practice, that analytical performance is reliable as confirmed by rigorous

TABLE 20.3 Properties and Applications of Less Commonly Requested Serum Tumor Markers

Tumor Marker	Biochemical Properties	Molecular Weight	Main Clinical Applications
Calcitonin	32-Amino acid peptide	~3.5 kDa	Monitoring medullary carcinoma of the thyroid
Cancer antigen 15.3 (CA 15.3), BR 27.29	Mucin (MUC-1 glycoprotein peptide) identified by monoclonal antibodies	>250 kDa	Monitoring breast cancer
Cancer antigen 19.9 (CA 19.9)	Glycolipid carrying the Lewis ^a blood group determinant	~1000 kDa	Monitoring pancreatic carcinoma following curative resection
Catecholamines	Biogenic amines	~0.2 kDa	See Chapter 26
Chromogranin A	Member of the granin family of acid secretory glycoproteins	~49 kDa	Monitoring neuroendocrine tumors
CYFRA 21-1	Fragments of cytokeratin 19	~30 kDa	Monitoring lung carcinoma
Gut hormones	Small peptide hormones including vasoactive intestinal peptide, pancreatic polypeptide, somatostatin, gastrin		See Chapter 38
Human epididymis protein 4 (HE4)	Product of the WFDC2 (HE4) gene that is overexpressed in patients with ovarian carcinoma	~25 kDa	Monitoring ovarian cancer. Potentially an aid in diagnosis as part of the risk of malignancy algorithm. Under evaluation
Inhibin A (α - β_A) Inhibin B (α - β_B)	Heterodimeric glycoproteins composed of an α - and a β -subunit. There are several forms of the β -subunit, as indicated	32 kDa	Monitoring of ovarian granulosa cell tumors and testicular Sertoli and Leydig tumors
β_2 -microglobulin	Component polypeptide chain of the HLA antigen complex	~12 kDa	Prognostic assessment of multiple myeloma
Neuron-specific enolase	Dimer of the enzyme enolase	~87 kDa	Monitoring small cell lung carcinoma, neuroblastoma, and neuroendocrine tumors
Placental alkaline phosphatase	Heat-stable isoenzyme of alkaline phosphatase	~86 kDa	Monitoring of germ cell tumors (seminomas)
Progastrin-releasing peptide	More stable precursor of gastrin-releasing peptide	~16 kDa	Monitoring small cell lung carcinoma
Prostate cancer gene 3 protein (PCA3)	Protein product of PCA3 gene in urine or prostate cancer patients	~86 kDa	Potentially an aid to diagnosis of prostate cancer particularly in biopsy-negative men. Under evaluation
Prostate marker algorithms	Phi	Not applicable	An algorithm combining serum measurements of total PSA, free PSA, and proPSA in serum
	4K	Not applicable	An algorithm combining serum measurements of free and total PSA, human kallikrein 2, and intact PSA
Squamous cell carcinoma antigen	Serine protease inhibitor isolated from glycoprotein subfraction of tumor antigen TA-4	48 kDa	Monitoring squamous cell carcinomas (e.g., cervix)
S-100 proteins	Family of proteins characterized by two calcium-binding sites that have helix-loop-helix confirmations	~20 kDa	Melanoma; clinical utility in melanoma to be established
Thyroglobulin	Glycoprotein dimer of two identical subunits	670 kDa	Monitoring differentiated thyroid cancer
Tissue polypeptide antigen	Fragments of cytokeratin 8, 18, and 19	~22 kDa	Monitoring bladder and lung carcinoma

PSA, Prostate-specific antigen.

TABLE 20.4 Tissue Markers Whose Measurement Informs Selection of Endocrine and Immunotherapy in Individual Patients

Tumor marker	Biochemical Properties	Molecular Weight	Main Clinical Applications
Anaplastic lymphoma receptor tyrosine kinase (<i>ALK</i>)	Enzyme encoded by the <i>ALK</i> gene	~176 kDa	Predicting response to the tyrosine kinase inhibitor) crizotinib in non–small cell lung cancer
<i>BRAF</i>	Proto-oncogene that encodes the serine/threonine protein kinase B-Raf	~87 kDa	Predicting response to inhibitors of <i>BRAF</i> -mutated protein including vemurafenib and dabrafenib in melanoma
Estrogen receptor	Nuclear transcription factor	~5 kDa	Predicting response to endocrine therapy in breast cancer
Human epidermal growth factor receptor-2 (HER2 or c-erb2)	Transmembrane glycoprotein encoded from <i>HER2/neu</i> oncogene	~185 kDa	Predicting response to trastuzumab (Herceptin) in breast cancer Predicting response to tyrosine kinase inhibitors in non–small cell lung cancer
<i>KRAS</i> mutation	Guanosine nucleotide-binding protein	~23 kDa	Predicting response to tyrosine kinase inhibitors in non–small cell lung cancer and reducing need for testing for <i>HER2</i> and <i>ALK</i> alterations
Progesterone receptor	Nuclear transcription factor	A form ~4 kDa B form: ~120 kDa	Predicting response to endocrine therapy in breast cancer

internal quality control (IQC) and proficiency testing (PT), and that postanalytical reporting of results to clinical users is both informed and informative.

Tumor Marker Validation

Assuming there is preliminary evidence that the marker has clinical potential, requirements for validation prior to introduction into routine use include:

1. *Protocols for sample collection and processing.* Availability of clinical specimens (e.g., serum, plasma, tissue) that have been collected, processed, and stored following validated standard operating procedures (SOP). The panel should include samples from patients with a variety of malignant and nonmalignant conditions. Specimens from biobanks may be appropriate provided their provenance is well documented.
2. *Analytical/technical validation.* Development and validation of each specific assay to be used in the clinic, having regard to the requirements described as follows, including biologic variation of the marker where feasible.
3. *Clinical validation.* Definition of the specific context in which the tumor marker is to be used so as to identify the type of specimens to be used in the clinical validation step, the informative statistics, and the acceptability criteria. Clinical validation should be reported in terms of diagnostic accuracy for tests intended for use in diagnosis. The risk of pitfalls including study bias, overfitting of data, and other statistical problems can be reduced by strict adherence to a written protocol and rigorous reporting of all work.
4. *Demonstration of clinical value.* Strong evidence that the test will benefit the patient (e.g., by increasing overall survival or leading to fewer invasive procedures or hospital visits). Ideally this should include high-level evidence from a prospective or retrospective randomized clinical trial or systematic review of the literature.

5. *Achieving regulatory approval.* Requirements vary but in the United States involve either clearance approval by the US Food and Drug Administration (FDA) and/or evaluation in a Clinical Laboratory Improvement Amendments (CLIA)-certified laboratory or by a laboratory-developed test pathway.
6. *Postmarket evaluation.* Analytical performance of the test in the routine clinical setting should be subject to continued evaluation, through rigorous implementation of IQC and PT procedures (refer to [Chapter 7](#)). Ongoing clinical audit to ensure that the marker retains its value in the clinical setting is also essential. When a newly introduced tumor marker replaces an earlier one, it is important to ensure that the first test is discontinued.

“Ideal” Tumor Marker

An “ideal” tumor marker should be the following:

1. Detectable only in a given malignancy and absent in the healthy population or in nonmalignant conditions (i.e., have clinical specificity and clinical sensitivity approaching 100%)
2. Present in a convenient biologic matrix (e.g., serum, urine, tumor tissue)
3. Present at concentrations proportional to tumor burden
4. Conveniently measured by a readily available, simple, reproducible, and inexpensive procedure
5. Beneficial to clinical care with a measurable effect on patient outcome

No such tumor marker has yet been identified. However, measurement of hCG approaches ideal in the screening and monitoring of women who have had a molar pregnancy and are at risk of developing gestational trophoblastic neoplasia (GTN) (choriocarcinoma). Other tumor markers can also contribute usefully to patient management provided they are used intelligently and with regard to requirements of the clinical application ([Tables 20.2 to 20.4](#)) as outlined next.

Clinical Applications of Tumor Markers

Screening for Cancer

Screening for disease differs fundamentally from diagnosis or “case finding” because the aim of screening is to detect unsuspected disease in asymptomatic subjects (Table 20.1). The World Health Organization (WHO) criteria for screening programs originally proposed by Wilson and Jungner in 1968 remain valid. High sensitivity and high specificity of the test for the target disease is essential, with the success of a screening program also dependent on the prevalence of the condition in the population being screened.

Diagnostic accuracy is established by studying test performance at different decision (cutoff) concentrations in appropriately selected diseased and disease-free populations. The relationship between these parameters is most conveniently depicted graphically as a receiver operating characteristic (ROC) plot. Changing the decision concentration selected alters both sensitivity and specificity but cannot improve both concurrently. These parameters define the characteristics of the test and, together with the prevalence of the disease in the population studied, yield its positive predictive value. The low prevalence of the majority of cancers, even in age groups most at risk, together with the low sensitivity and specificity of most tumor markers, generally precludes their use in screening. However, screening for early colorectal cancer using a fecal immunochemical test (FIT) for hemoglobin is routine in some countries, the efficacy of screening patients at high risk of hepatocellular carcinoma (HCC) and ovarian cancer is being actively investigated, and there is continuing debate about whether to screen for prostate cancer and some genetic conditions.

Diagnosis of Cancer

The lack of sensitivity and specificity that limits the application of tumor markers in screening also applies to diagnosis and case finding (Table 20.1). Tumor markers are not helpful for diagnosis in patients with nonspecific symptoms and cannot replace biopsy for establishing a cancer diagnosis. However, in carefully selected undiagnosed patients, raised concentrations of tumor markers may contribute to diagnosis (e.g., when the patient is unable or unwilling to undergo more invasive testing such as colonoscopy). In general, the higher the serum tumor marker value the greater the likelihood of malignancy, but results within the reference interval never necessarily exclude malignancy. Requests for panels of tumor marker measurements should be actively discouraged, as should requests for prostate-specific antigen (PSA) in women or CA 125 in men.

Assessing Prognosis

Prognostic markers predict the likely outcome of disease with respect to risk of relapse or disease progression (Table 20.1). They are generally most useful at the time of initial diagnosis, when a marker of good prognosis is suggestive of prolonged survival and/or the possibility of cure. A marker of poor prognosis indicates an increased probability of early recurrence.

Prognostic markers can help identify patients with aggressive tumors that require further treatment (e.g., with systemic adjuvant chemotherapy following surgery) while minimizing the risk of overtreatment of patients with indolent disease that is unlikely to progress. Few prognostic markers are used in routine clinical practice as they provide a probability estimate of outcome for a heterogeneous population rather than for an individual patient. Most of those used are measured in tissue. Exceptionally, measurement of AFP, hCG, and lactate dehydrogenase (LDH) in serum or plasma following primary surgery in patients with nonseminomatous germ cell tumors (GCTs) is mandatory. These well-validated markers provide strong independent prognostic information complementing that of conventional prognostic factors.

Prediction of Treatment Response

Even cancers of the same histologic type may vary widely in response to a particular treatment, and for most cancers only a subset of patients will respond (Table 20.1). Predictive markers that can identify such patients are therefore critical in treatment planning, so that treatment can be offered to patients who will benefit and enabling alternative treatment to be offered to those who will not, also sparing them unnecessary side effects. Predictive markers, most of which are measured in tissue rather than serum, are increasingly both clinically and economically essential to identify patients who may benefit from new and costly molecularly targeted treatments. Several important predictive markers for breast cancer are already well established in clinical use, with further promising markers now available for breast cancer, colorectal cancer, glioma, melanoma, and non-small cell lung cancer (NSCLC).

Monitoring Response During and/or Shortly After Treatment

The main application of most serum tumor markers is in monitoring the course of disease. In general, it is helpful to measure the relevant tumor marker pretreatment to provide a baseline for subsequent interpretation, and for some cancers measurements made during and immediately after treatment are also desirable. In general, a decrease in marker concentrations to within “normal” limits following treatment is a favorable sign. In some cases, subnormal or absent posttreatment values should be achieved (e.g., for PSA post prostatectomy or thyroglobulin following thyroid ablation). Measurement of AFP and hCG is mandatory for GCTs prior to surgical excision, to enable calculation of the half-life of tumor marker decline following chemotherapy.

Monitoring Disease Post Treatment to Detect Progression or Recurrence

Serial monitoring of tumor marker concentrations post treatment provides early indication of disease progression, often months before there are clinical signs and symptoms. Whether this information is of benefit depends crucially on whether the increase will prompt clinical action (e.g., early ultrasound, computed tomography (CT), or magnetic resonance imaging [MRI] scanning), whether alternative treatment

is available and/or whether that treatment can be implemented without confirmatory scan evidence. If not, and if the patient is not enrolled in a clinical trial, the patient should be made aware of the potential implications of having the test done, and whether tumor marker monitoring is likely to be of benefit should be seriously considered and discussed.

QUALITY REQUIREMENTS FOR TUMOR MARKER USE IN THE CLINIC

The clinical laboratory should provide readily available information to those requesting tumor markers, to encourage selection of the correct test or tests (and, importantly, to discourage inappropriate requesting) and to ensure that specimen timing is appropriate and other preanalytical requirements are met. Ensuring that results are analytically correct and that accurate and informative reports are returned to the requesting clinician are also laboratory responsibilities. Laboratory-oriented guidelines for tumor markers that outline quality requirements for provision of a high-quality tumor marker service have been developed by the NACB and form the basis of the following discussion.

Pre-preanalytical Requirements

Although numerous serum tumor markers can be measured (Tables 20.2 to 20.4), relatively few are commonly requested from the clinical laboratory. Table 20.5 summarizes the current recommendations of the NACB for their appropriate clinical use, and typical clinical presentations that might prompt a request are described in Table 20.6.

Requests for tumor markers may be for diagnosed cancer patients who have already been referred to specialist centers and are being or have been treated, for patients who have been referred to hospital for investigation of suspected malignancy and further investigation, and for patients who have presented to their family doctor with symptoms suspicious for malignancy. Requests in the first category (with a baseline measurement prior to therapy always desirable) are most likely to be appropriate.

Nonspecialist users should always consider carefully whether a tumor marker result is likely to be helpful before making a request. Requestors should be aware of the lack of sensitivity of most tumor markers, particularly for early stage disease, their lack of specificity, and the numerous nonmalignant conditions in which they may be increased (Table 20.7). Nonspecialist users should also be aware that increased tumor marker concentrations do not necessarily indicate malignancy. Attempting to identify the reason for an increased tumor marker that should never have been requested and may not be associated with malignancy can be expensive and time consuming, and psychologically stressful for the patient. Conversely, requestors should be reminded that a result within the reference interval never necessarily excludes malignancy or progressive disease. Clinical biochemists should also think carefully before requesting additional tests that might lead to a diagnosis of malignancy and should seek the agreement of the clinician caring for the patient before doing so.

Unfocused requests such as “tumor marker screen” or “malignancy?” should be actively discouraged and met with offers for educational support. Advice about appropriate test selection should be made readily available at the time of requesting, ideally electronically.

Preanalytical Requirements

Specimen Timing

Timing of specimens within the day for tumor marker measurement is not usually critical because there is little evidence of diurnal variation for most markers. A pretreatment specimen is always helpful when interpreting subsequent results. Specimens should be taken before some procedures that may transiently release tumor markers into the circulation (e.g., CA 125 following abdominal surgery, CEA following colonoscopy, and PSA after prostatic biopsy or digital rectal examination [DRE]). Awareness of benign conditions that may cause transient increases in tumor marker concentrations (Table 20.7) and avoiding inappropriate timing reduces the risk of misinterpreting spuriously raised results that may cause undue distress to the patient and also decrease confidence in laboratory testing.

Specimen Handling

Serum and/or plasma specimens are appropriate for most tumor marker measurements, although gel tubes may not be suitable for some assays. Requirements should be checked in the product information supplied. Tumor markers are generally stable, but serum or plasma should be separated from the clot as soon as possible and then stored at 4°C (short term) or –30°C or below. For longer-term storage, specimens should be stored at –70°C or below. Standardized conditions of specimen collection and fixation are crucial for immunohistochemical analyses.

Analytical Requirements

Assay Validation

Prior to introduction into routine clinical practice, both immunoassays and immunohistochemical methods must be validated, as described previously, by defined and well-characterized protocols that meet regulatory guidelines (e.g., FDA approval in the United States and CE marking in Europe). Individual laboratories should verify analytical performance prior to introduction into routine use. Internationally recognized guidelines for the performance of immunohistochemical tests should be adopted if available and methods described in detail if appropriate high-quality reference materials are not available.

Internal Quality Control

Robust procedures for IQC should be established. Within-run variability less than 5% and between-run variability less than 10% should be readily achievable for automated tumor marker methods. Some newer techniques may perform significantly better than this, although manual and/or research assays may be less precise. Appropriate action should be taken immediately if an assay run fails to meet objective criteria for assay acceptance so that no potentially erroneous results are reported. Criteria for acceptance should be predefined and preferably based on logical criteria such as those of Westgard.

TABLE 20.5 Most Frequently Requested Serum Tumor Markers and National Academy of Clinical Biochemistry Recommendations for Their Appropriate Clinical Use

	Relevant Cancer	CURRENTLY RECOMMENDED CLINICAL APPLICATIONS				
		Screening or Early Detection	Diagnosis or Case Finding	Prognosis (With Other Factors)	Detecting Recurrence	Monitoring Therapy
AFP	Germ cell/testicular tumor	✓ ^a	✓	✓	✓	✓
	HCC		✓ ^b	✓	✓	✓ ^c
Calcitonin	Medullary thyroid carcinoma		✓		✓	✓
CA 125	Ovarian cancer	✓ ^d	✓ ^e	✓	✓	✓ ^f
CA 15-3	Breast cancer				✓ ^g	✓ ^h
CA 19-9	Pancreatic cancer		✓ ⁱ	✓	✓	✓ ^j
CEA	Colorectal cancer			✓	✓ ^c	✓ ^{c,h}
hCG	Germ cell and testicular cancers; gestational trophoblastic neoplasia ^k		✓	✓	✓	✓
Paraproteins (M protein/Bence Jones protein) (Also measured in urine)	Multiple myeloma		✓		✓	✓
Prostate-specific antigen	Prostate cancer		✓	✓	✓	✓
Thyroglobulin	Thyroid cancer (follicular or papillary)				✓	✓

^aOnly for subjects in high-risk groups (e.g., with chronic hepatitis B virus, hepatitis C virus, or cirrhosis) and only in conjunction with ultrasound (impact on mortality unclear).

^bIn conjunction with liver imaging, AFP levels >200 µg/L are regarded as virtually diagnostic of HCC in patients with hypervascular lesions.

^cEspecially for disease that cannot be evaluated by other modalities.

^dOnly for women at high risk of ovarian cancer and only in conjunction with transvaginal ultrasound.

^eOnly for differential diagnosis of pelvic masses, especially in postmenopausal women.

^fPreliminary results of a randomized trial show no survival benefit from early treatment based on a raised serum CA 125 level alone so this recommendation may be modified to exclude asymptomatic patients.

^gPost surgery when may provide lead time for early detection of metastasis but clinical value unclear.

^hEspecially in patients with nonevaluable disease (for which CEA is also recommended in carefully selected patients).

ⁱIn patients in whom pancreatic disease is strongly suspected, CA 19-9 may complement other diagnostic procedures.

^jEspecially after chemotherapy and in combination with imaging.

^kUse of hCG in screening for gestational trophoblastic neoplasia, a rare malignancy that develops most frequently following a molar pregnancy provides an excellent example of “best practice” in screening. Further information is available from the Trophoblastic Tumour Screening and Treatment Centre, Department of Medical Oncology, Charing Cross Hospital, London W6 8RF, UK (Tel: +44 (0) 20 8846 1409) or at <http://www.hmole-chorio.org.uk/>.

AFP, α-Fetoprotein; CA 125, cancer antigen 125; CA 15-3, cancer antigen 15-3; CA 19-9, cancer antigen 19-9; CEA, carcinoembryonic antigen; HCC, hepatocellular carcinoma; hCG, human chorionic gonadotrophin.

TABLE 20.6 Typical Clinical Presentations That Might Prompt a Request for the Most Frequently Used Tumor Markers^a

Tumor Marker	Relevant Cancer	Typical Clinical Presentation	Other Cancers in Which Marker May Be Raised ^b
α-Fetoprotein	Germ cell/testicular tumor Hepatocellular carcinoma	Diffuse testicular swelling; hardness Ascites, encephalopathy, jaundice; upper abdominal pain; weight loss; early satiety in high-risk subjects (i.e., hepatitis B- or C-related cirrhosis)	Gastric; colorectal; biliary; pancreatic; lung

Continued

TABLE 20.6 Typical Clinical Presentations That Might Prompt a Request for the Most Frequently Used Tumor Markers^a—cont'd

Tumor Marker	Relevant Cancer	Typical Clinical Presentation	Other Cancers in Which Marker May Be Raised^b
Cancer antigen 125	Ovarian cancer	Pelvic mass; persistent, continuous or worsening unexplained abdominal or urinary symptoms; bloating	Breast; endometrial; cervix; peritoneal; uterus; lung; pancreas; hepatocellular; non-Hodgkin lymphoma
Cancer antigen 19-9	Pancreatic cancer	Progressive obstructive jaundice with profound weight loss and/or pain in the abdomen or mid-back	Colorectal; gastric; hepatocellular; esophageal; ovary
Carcinoembryonic antigen	Colorectal cancer	Intermittent abdominal pain, nausea, vomiting or bleeding; palpable abdominal mass	Breast; gastric; lung; mesothelioma; esophageal; pancreas
Human chorionic gonadotrophin	Germ cell/testicular tumor Gestational trophoblastic neoplasia	Diffuse testicular swelling, hardness, and pain Symptoms leading to x-ray showing cannon ball secondaries; previous history of hydatidiform mole	Lung cancer
Paraproteins (M protein/ Bence Jones protein) (Also measured in urine)	Multiple myeloma	Combination of symptoms including some/all of the following: anemia; back pain; weakness or fatigue; osteopenia; osteolytic lesions; raised ESR or globulins; spontaneous fractures; recurrent infections	
Prostate-specific antigen	Prostate cancer	Frequency, urgency, nocturia, dysuria; acute retention; back pain, weight loss, anemia	None

^aTumor markers are often not helpful in diagnosis (see text).

^bThis list is not comprehensive. The marker may be raised in other cancers.

TABLE 20.7 Nonmalignant Conditions That May Cause Increases (Some Transient) in Serum Tumor Marker Concentrations That May Lead to Incorrect Interpretation^a

Acute cholangitis	CA 19-9
Acute hepatitis	CA 125, CA 15-3
Acute and/or chronic pancreatitis	CA 125, CA 19-9
Acute urinary retention	CA 125, PSA
Arthritis/osteoarthritis/rheumatoid arthritis	CA 125
Benign prostatic hyperplasia	PSA
Cholestasis	CA 19-9
Chronic liver diseases (e.g., cirrhosis, chronic active hepatitis)	CEA, CA 125, CA 15-3, CA 19-9
Chronic renal failure	CA 125, CA 15-3, CEA, hCG
Colitis	CA 125, CA 15-3, CEA
Congestive heart failure	CA 125
Cystic fibrosis	CA 125
Dermatologic conditions	CA 15-3
Diabetes	CA 125, CA 19-9
Diverticulitis	CA 125, CEA
Endometriosis	CA 125
Heart failure	CA 125
Irritable bowel syndrome	CA 125, CA 19-9, CEA
Jaundice	CEA, CA 19-9
Leiomyoma	CA 125
Liver regeneration	AFP
Menopause	hCG
Menstruation	CA 125
Mesothelioma	CEA
Nonmalignant ascites	CA 125
Ovarian hyperstimulation	CA 125
Pancreatitis	CA 125, CA 19-9
Pericarditis	CA 125

TABLE 20.7 Nonmalignant Conditions That May Cause Increases (Some Transient) in Serum Tumor Marker Concentrations That May Lead to Incorrect Interpretation^a—cont'd

Peritoneal inflammation	CA 125
Pregnancy	AFP, CA 125, hCG
Prostatitis	PSA
Recurrent ischemic strokes in patients with metastatic cancer	CA 125
Respiratory diseases (e.g., pleural inflammation, pneumonia)	CA 125, CEA
Sarcoidosis	CA 125
Systemic lupus erythematosus	CA 125
Urinary tract infection	PSA

^aThis list is not comprehensive; these markers may be raised in other nonmalignant conditions.

AFP, α -Fetoprotein; CA 125, cancer antigen 125; CA 19-9, cancer antigen 19-9; CEA, carcinoembryonic antigen; hCG, human chorionic gonadotropin; PSA, prostate-specific antigen.

Given the long-term monitoring involved in cancer care, assay stability should be ensured over prolonged periods.

Quality control (QC) material not provided by the method manufacturer is preferable because kit controls may provide an overly optimistic impression of performance. At least one authentic serum matrix control from an independent source should be included in addition to QC materials provided by the manufacturer. Negative and low positive controls should be included for all tumor markers and should include concentrations close to important decision points (e.g., 0.1 and 3 or 4 $\mu\text{g/L}$ for PSA; 4 to 7 $\mu\text{g/L}$ for AFP; 5 U/L for hCG). The broad concentration range should be covered, and ideally a high concentration control should occasionally be included to check the accuracy of dilution, whether manual or on-board.

Proficiency Testing/External Quality Assessment

PT specimens should ideally be prepared from authentic patient sera, which for tumor markers may require dilution of high-concentration patient sera into a normal serum base pool. PT specimens should be commutable with patient specimens to ensure valid between-method comparisons. Specimens prepared by spiking purified analyte into serum base pools are likely to provide an overly optimistic impression of between-method performance. Specimens should assess performance over the working range and include assessment of linearity on dilution, baseline security, and stability of results.

Standardization

Major international efforts continue to be directed toward encouraging manufacturers to calibrate their methods accurately in terms of commutable International Standards (IS) or reference reagents, where available. Improved understanding of what is being measured is also critical if improved comparability is to be achieved. Manufacturers should provide clear information about the specificity of the antibodies used in their methods and data on cross-reactivity that is readily comparable with that of other methods so that users are aware of the differences.

Despite major international efforts to improve comparability, the molecular heterogeneity of most tumor markers means that results obtained using different methods are not interchangeable and considerable care is required in the interpretation of serial results obtained using more than one method.

Fig. 20.1 Schematic illustration of high-dose hooking in tumor marker immunoassays. The extremely high tumor marker concentration blocks antibody-binding sites in the immunoassay such that the apparent result “hooks” back onto the calibration curve and an erroneously low result may be reported. [See text and Chapter 15 for further details.]

Clinically Relevant Interferences

Tumor marker measurements are subject to the same interferences as all immunoassays, but the following are particularly relevant:

High-dose “hooking.” As tumor marker concentrations can range over several orders of magnitude, protocols enabling identification of high-dose “hooking” are essential to minimize the risk of reporting erroneously low results, particularly in patients for whom markers are being measured for the first time. An example is shown in Fig. 20.1. The risk of “hooking” is reduced by using solid phase antibodies of higher binding capacity, by using sequential assays that include a wash step, and by assaying specimens at two dilutions. Methods vary in their vulnerability to this interference (for additional information, refer to Chapter 15).

Specimen carry-over. Specimen carry-over is possible whenever high concentration specimens are assayed, so it is desirable to check periodically for this possibility. Serum concentrations of hCG can be greater than 1,000,000 U/L, so carry-over as low as 1/10,000 can still lead to a falsely positive result in the following sample.

Interference from heterophilic or human anti-mouse antibodies. Some patient sera contain anti-immunoglobulin (Ig)

antibodies (most often IgG) that may react with immunoassay reagent antibodies. High concentrations of human anti-mouse antibodies (HAMAs) may also be present in serum from cancer patients who have received treatment with mouse monoclonal antibodies for imaging or therapeutic purposes. For either interference, results may be falsely high or low. Identifying such interference requires a high degree of clinical suspicion, which is facilitated by availability of relevant clinical details. Possible interference can be investigated by assaying the specimen at several dilutions, by reassaying after treatment with a commercially available blocking agent, by adding further nonimmune mouse serum to the reaction mixture and reassaying, and/or by reassaying the specimen using a different method and preferably a different methodology. Caution should be applied in interpretation. For example, linearity on dilution does not always exclude the presence of HAMAs (for additional information, refer to [Chapter 15](#)).

Postanalytical Requirements

Brief information on the request form about the source of the suspected or diagnosed malignancy and the treatment stage (e.g., preoperative, postoperative, prechemotherapy) is highly desirable. This information should be recorded both in the laboratory computer and on the laboratory report. Reports should include cumulative and, if possible, graphical presentation of results because trends in tumor marker results are generally most informative. Such reporting facilitates interpretation of results and can also help to identify occasional errors in requesting or in the laboratory (e.g., incorrect sample identification or missampling on an analyzer), as well as highlighting unexpected results (e.g., sudden changes that are out of accord with the clinical picture) that require confirmation and further investigation. Brief comments relating to interpretation of the analytical results (e.g., whether an increase is likely to be clinically significant or not) and helpful advice about the frequency of monitoring and the need for confirmatory specimens is also desirable.

Urgent results that may be required for immediate patient management should be identified by the reporting biochemist so as to ensure that these reach the relevant clinician promptly (e.g., by telephone). These include tumor marker results that can be used to diagnose advanced disease in critically ill but treatable patients (e.g., AFP in hepatoblastoma, hCG in choriocarcinoma, AFP and hCG in nonseminomatous GCT, and PSA in men with advanced prostate cancer). The consequences of failure to telephone such results can be severe.

In view of the method-related differences discussed previously and as recommended by the NACB, the method used should be stated on the clinical report so that changes of method are readily identifiable. If there has been a method change, it is highly desirable that the laboratory indicates whether this is likely to influence interpretation of the trend in results. There should be a defined protocol for method changes and the likely effect communicated to clinical users prior to the change. Managing the change may necessitate analyzing the previous specimen by the new method or requesting a further specimen to reestablish the baseline and/or confirm the trend in marker concentrations.

Reference intervals should be derived using an appropriate healthy population and should ideally be specific to the method

used. They are usually most relevant for cancer patients pretreatment because subsequently the patient's individual "baseline" results provide the most important reference point for most marker results. Provided "baseline" marker concentrations are well established in diagnosed patients post treatment, sustained increases even within the reference interval may be significant and should be treated as possible relapse.

The percentage increase or decrease that constitutes a significant change should be defined and should take account of analytical and biologic variation, as well as the time between samples. For tumor markers a confirmed increase or decrease of $\pm 25\%$ is frequently considered to be clinically significant.

Laboratories should be able to provide calculated tumor marker half-lives or doubling times for markers for which these are relevant (e.g., AFP and hCG). Half-lives are defined as the time to 50% reduction of circulating tumor marker concentration following complete removal of tumor tissue. Their calculation may be irrelevant if a 50% reduction does not represent a significant change. (See Germ Cell Tumor section for calculation details.)

Proactive provision of a high-quality tumor marker service helps to encourage good communication between laboratory and clinical staff and is likely to encourage appropriate use of tumor marker tests, as well as early identification of any results that are not in accord with the clinical picture and require investigation. An example of a laboratory report that fulfills many of these requirements is shown in [Fig. 20.2](#).

POINTS TO REMEMBER

- Cancer is a heterogeneous disease that is a leading cause of death, although death rates for individual cancers vary markedly and there have been considerable advances in treatment over recent decades.
- Tumor markers are surrogate indicators that can help to make or confirm a cancer diagnosis, monitor treatment effectiveness and the course of disease, estimate prognosis, and/or predict whether a specific therapy is likely to be effective.
- Optimal use of tumor markers requires an evidence-based approach to clinical decision making and knowledge of the limitations of these tests particularly in relation to clinical sensitivity and specificity.
- Tumor marker results are rarely diagnostic and cannot replace biopsy for the primary diagnosis of cancer.
- Tumor marker measurements are not recommended for patients with vague symptoms when the population likelihood of cancer is low.
- A raised tumor marker result never necessarily indicates malignancy, and conversely a result within the reference interval never necessarily excludes malignancy.
- In diagnosed patients a pretreatment result is essential and provides the baseline against which subsequent results can be assessed.
- Tumor marker results should always be confirmed on a repeat specimen if decisions about therapy depend on the result.
- Tumor marker results should always be interpreted in the context of all available information, and the possible influence of other factors (e.g., medication, analytical effects) should be carefully considered.

Fig. 20.2 Schematic diagram of a desirable clinical laboratory report for tumor markers that fulfills current reporting recommendations.

Use of Tumor Markers in Specific Malignancies

The extent to which tumor markers currently contribute to the management of a number of important malignancies is briefly reviewed in the following sections.

Bladder Cancer

Approximately 600,000 Americans are currently affected by bladder cancer, with 74,000 new cases diagnosed each year. The most common symptom is intermittent hematuria, which is present in 80% to 85% of patients, with voiding problems or dysuria also common. Transitional cell carcinomas (TCCs) account for the majority of bladder cancers, but adenocarcinomas, squamous cell carcinomas, and sarcomas occur. Diagnosis is usually established by cystoscopic evaluation. Primary treatment is complete surgical resection, usually by transurethral resection with or without additional immunotherapy, chemotherapy, or radiotherapy. There is a high risk of recurrence, and 50% to 70% of patients will develop tumor recurrence within 5 years, depending on the stage of disease. Lifelong surveillance is therefore required.

Tumor Markers Relevant to Bladder Cancer

Markers evaluated for bladder cancer include nuclear matrix proteins (NMPs), human complement factor H-related protein, fibronectin, telomerase, cytokeratins, and survivin. NMPs make up the internal structure of the nucleus and contribute to the regulation of some of the key functions that occur in the nucleus.

The FDA has approved an enzyme-linked immunosorbent assay (ELISA) for the measurement of nuclear mitotic apparatus protein, a component of the nuclear matrix that is overexpressed in bladder cancer. Approved uses of the NMP-22 test are as an aid in the diagnosis of symptomatic patients or those with risk factors suggesting TCC and in the management and monitoring of patients with TCC. A qualitative point-of-care version of the test is available as an aid in monitoring patients with a history of bladder cancer.

The bladder tumor-associated antigens (BTAs), human complement factor H-related protein, and related proteins are involved in the regulation of the alternative pathway of complement activation that prevents complement-mediated damage to healthy cells. The BTA-Trak and BTA-Stat tests have been approved by the FDA for use in conjunction with cystoscopy in the management of bladder cancer patients.

Breast Cancer

Breast cancer is the most common cancer in women worldwide, affecting 10% to 12% of women. In symptomatic women the main presenting features include a lump in the breast, nipple change or discharge, and skin contour changes. Worldwide the incidence appears to be increasing, but in some Western countries mortality rates are declining. This decrease has been attributed to earlier detection by systematic screening with mammography, greater awareness among women of early signs of breast cancer, and availability of adjuvant treatment for newly diagnosed cases. In the United States, breast cancer represents approximately 14% of all new cancer cases and nearly 3 million women are living with the disease. For the approximately 60% of breast cancer patients in the United States who have localized disease at diagnosis (i.e., confined to the primary site), the 5-year survival rate is 98.6% as compared with 25.9% for the 6% of patients who have distant metastases at diagnosis.

Primary treatment for localized breast cancer is either breast-conserving surgery and radiation or mastectomy. Following primary treatment, most women with invasive breast cancer receive systemic adjuvant such as chemotherapy, hormone therapy, or immunotherapy or a combination of these. Depending on estrogen receptor (ER) status and other factors, not all patients with breast cancer require adjuvant treatment.

Tumor Markers Used in the Management of Breast Cancer

Tissue tumor marker measurements essential for the management of breast cancer include those for receptors for estrogen, progesterone, and HER2, and CA 15-3 and the closely related BR 27.29 are the serum markers of choice. Measurement of CEA may also be helpful in patients with metastatic breast cancer. In early-stage disease, concentrations of CA 15-3 may be similar to those found in healthy women or women with benign breast disease.

Screening and Diagnosis. Early detection undoubtedly improves 5-year survival, but the low specificity and sensitivity of currently available serum tumor markers, especially in early stage disease, preclude their use in screening for breast cancer, and x-ray imaging with mammography remains the only screening modality.

Women at increased risk of breast cancer because of a strong family history of breast cancer (e.g., relatives diagnosed at a young age) or because they are carriers of the *BRCA1*, *BRCA2*, or *TP53* genetic mutations are likely to benefit from additional screening with MRI, which is current policy in the United Kingdom.

Definitive diagnosis of breast cancer requires biopsy and histology. Serum tumor markers do not contribute to this, but preoperative measurements of CA 15-3 and/or CEA are desirable if either marker is going to be used for posttreatment monitoring. A high CA 15-3 concentration (e.g., >40 to 50 kU/L) in a patient with apparently localized breast cancer should prompt further investigation to exclude the possibility of metastatic disease.

Prognosis. Accurate assessment of **prognosis** is essential for optimal management of breast cancer patients so as to avoid undertreatment of patients with advanced disease and overtreatment of patients with indolent disease. The extracellular serine protease urokinase plasminogen activator (uPA) and its endogenous inhibitor plasminogen activator inhibitor 1 (PAI-1) are the best validated tissue prognostic markers for breast cancer but are not currently widely used in clinical practice.

Multigene Profiling in Prognosis. Several gene expression profiles or multigene panels have been proposed for determining prognosis in breast cancer patients. The Oncotype DX test measures the expression of 16 cancer-associated and 5 control genes in breast tumor tissue at the RNA level and stratifies newly diagnosed patients with invasive breast cancer as being at low, medium, or high risk of recurrence.

Other gene profiles include the MammaPrint test, which measures the expression of 70 genes involved in signal transduction pathways responsible for breast cancer metastasis. MammaPrint is approved by the FDA to assist in assignment of women with ER-positive or ER-negative breast cancer into high- or low-risk groups for recurrence.

Preoperative serum concentrations of CA 15-3 predict shortened disease-free or overall survival in breast cancer patients and can provide additional prognostic information, perhaps because the marker is detecting micrometastases or occult disease that is not clinically evident. Because CA 15-3 measurement is relatively convenient and inexpensive, it may be appropriate to use it when planning optimal treatment of newly diagnosed patients with breast cancer, but further evaluation is required.

Therapy Prediction. Measurement of ER, the longest-established molecular marker for breast cancer, is mandatory in all newly diagnosed invasive breast cancer patients to determine whether anti-estrogen endocrine therapy is likely to be effective. Patients with ER-positive tumors tend to respond to hormonal therapy, whereas those with ER-negative tumors will be treated using chemotherapy or other therapies. The negative predictive value of ER is high (i.e., patients who are ER negative are very unlikely to benefit from endocrine therapy). However, in both early and advanced breast cancer, its positive predictive value is less accurate.

Patients with breast cancers that overexpress the *HER2* gene are candidates for treatment with anti-HER2 immunotherapies, which have been cleared by the FDA. Because amplification of the *HER2* gene occurs in only 20% of patients with invasive breast cancers, it is important to identify these patients so as to avoid treating patients unlikely to respond.

Detailed recommendations and good practice guidelines for measurement of ERs and progesterone receptors (PRs) have been published by the American Society for Clinical Oncology (ASCO) and the College of American Pathologists (CAP) and endorsed by the NCCN.

Monitoring. Most women who have been treated for breast cancer, with or without adjuvant therapy and/or curative surgery, are subsequently evaluated at regular intervals with history, physical examination, and annual mammography. The aim of follow-up is to identify early recurrence or metastatic disease on the assumption that early intervention will improve survival. If serum tumor markers are measured, CA 15-3, CEA, and/or BR 27.29 are the markers of choice.

However, the clinical value of serial measurements of CA 15-3 and other tumor markers is unclear. Their regular measurement can provide a lead time of 5 to 6 months, but whether early intervention based solely on tumor marker increase alone improves outcome is not well established and guideline recommendations vary. The NACB states that tumor markers can be measured where other methods of evaluation are not possible. The NCCN includes rising CA 15-3, CEA, and/or BR 27.29 in its definition of disease progression and states that marker increases raise the suspicion of tumor progression, also cautioning that such increases may be seen in responding disease. ASCO states that these markers may be used as adjunctive assessments, but not alone, to contribute to decisions regarding therapy in women with metastatic breast cancer. The Southwest Oncology Group is undertaking a prospective clinical trial to evaluate the impact of serial testing.

Cervical Cancer

Cervical cancer is the fourth most common cancer in women worldwide and a leading cause of cancer death in women in the developing world, where 85% of cases occur. In the United States, 12,360 new cases were diagnosed in 2014 and 4020 patients died of the disease. The most important factor in the development of cervical cancer is persistent infection with human papillomaviruses (HPVs). Primary prevention is therefore feasible with prophylactic vaccination.

Most women are asymptomatic and are frequently diagnosed only after abnormal cervical cytology is identified in a screening program. Introduction of widespread cytology screening in the United States decreased the incidence of cervical cancer from 14.8 per 100,000 women in 1975 to 6.6 per 100,000 in 2008, with a similar reduction in mortality. HPV testing is gradually being added to screening programs in a number of countries. Women with higher-grade abnormalities identified by cytology are referred immediately for colposcopy, whereas for low-grade or borderline cell abnormalities, the sample is automatically tested for HPV.

Treatment planning of patients with cervical cancer is primarily determined by the clinical stage of the disease and histologic type. Early-stage disease can be treated by radical hysterectomy and pelvic lymphadenectomy or radiotherapy. For more advanced disease, chemoradiation or neoadjuvant chemotherapy may also be required.

Tumor Markers Used in the Management of Cervical Cancer

Squamous cell carcinoma antigen (SCCA) is the serum tumor marker of choice for squamous cell cervical

carcinoma, whereas CEA and CA 125 may have possible utility in patients with cervical adenocarcinoma. Serum SCCA concentrations correlate with tumor stage, tumor size, residual tumor post treatment, recurrent or progressive disease, and survival in patients with squamous cell cervical carcinoma. However, whether serum SCCA measurements are useful in clinical practice remains uncertain. There is no evidence that earlier detection of recurrent disease through tumor marker monitoring influences outcome or prognosis. Consequently, no currently available serum tumor markers are recommended for routine clinical use in patients with cervical cancer.

Colorectal Cancer

Colorectal cancer is the second leading cause of cancer-related death both worldwide and in the United States, where it is also the fourth most frequently diagnosed cancer. Typical symptoms include altered bowel habit, weight loss, anemia, and fecal occult blood. The natural history of the disease involves slow multistage progression from mucosal cell hyperplasia through adenoma formation, growth, and dysplasia, followed by malignant transformation and invasive cancer. In the United States, 5-year survival is approximately 90% for locally confined tumors, approximately 70% for those that have spread regionally, but only approximately 10% if distant metastases are present, highlighting the importance of detecting early-stage disease.

Tumor Markers Used in the Management of Colorectal Cancer

CEA, an oncofetal antigen first identified as being associated with colorectal cancer in the 1960s, remains the most relevant serum tumor marker for colorectal cancer.

Screening for Colorectal Cancer Using Tumor Markers.

Several randomized controlled trials have shown that population-based screening using fecal occult blood testing (FOBT) can reduce mortality from colorectal neoplasia, with an average reduction in mortality of at least 16%. Based on this evidence, a number of countries have introduced screening for colorectal cancer, replacing the early guaiac-based tests with newer FIT that detect the globin component of hemoglobin. Because both types of test lack specificity for colorectal cancer, follow-up colonoscopy is required for positive tests.

Typically, patients collect fecal samples at home on a card that is mailed to a central testing laboratory for either test. FITs are easier to use than guaiac-based tests for a number of reasons. They can be automated, provide quantitative rather than qualitative results with adjustable cutoff points, are less vulnerable to interference (e.g., due to diet or drugs), have greater analytical specificity and better clinical sensitivity for cancers and advanced adenomas, and are cost effective. Ease of use is particularly important as the success of any screening program depends on its acceptability to the population being screened and consequently its uptake.

Analysis of genetic and/or epigenetic markers in fecal material forms the basis of an automated DNA screening test for colorectal cancer that has been approved by the FDA.

Individuals with a strong family history of colorectal cancer, hereditary nonpolyposis colon cancer (Lynch syndrome), or familial adenomatous polyposis (FAP) are at high risk of developing colorectal cancer and should be referred for risk assessment and endoscopic screening according to agreed protocols. Genetic counseling and germline gene testing for Lynch syndrome should be offered to patients or microsatellite instability (MSI) or mismatch repair (MMR) gene mutations.

Diagnosis. The low clinical sensitivity of CEA, particularly for early-stage disease, precludes its use in diagnosis. It will be increased in only 30% to 50% of patients at the time of diagnosis and cannot be used in isolation to diagnose even advanced disease. Its specificity is also low because it can be increased in nonmalignant liver and renal disease, as well as in other malignancies. However, clearly increased concentrations can assist in diagnosis in certain clinical circumstances and may be suggestive of metastatic disease, although they do not necessarily indicate a colorectal primary.

Prognosis, Staging, and Therapy Prediction. Increased preoperative CEA concentrations at the time of initial presentation of patients with colorectal cancer are associated with adverse outcome and can provide both prognostic information and a baseline value for interpreting subsequent results.

Patients with advanced colorectal cancer may be treated with anti-EGFR monoclonal antibodies, which bind to the extracellular domain of EGFR. Patients with a specific mutation of the *KRAS* gene appear to benefit most from such treatment, and modeling studies suggest that administering anti-EGFR antibody treatment only to patients with wild-type *KRAS* would result in significant net cost savings.

Monitoring. Meta-analyses of a number of randomized controlled trials designed to compare intensive follow-up with minimal follow-up of colorectal cancer patients following curative resection have demonstrated that intensive follow-up, which includes CEA, improves overall survival. It is now recommended that CEA testing should be performed every 3 to 6 months for 5 years following curative surgery for colorectal cancer, although results within the reference interval do not necessarily exclude progression.

An increase in CEA should prompt referral for early investigation of possible recurrence but should be confirmed by a second sample taken within approximately 1 month. What constitutes a significant increase in CEA is not yet well established. An elevation at least 30% over that of the previous concentration is regarded by some groups as significant, whereas smaller consecutive increases (e.g., 15% to 20%) observed on at least three successive occasions with intervals of at least 2 weeks between them may also prompt intervention.

Resection of metastatic deposits in the liver is an option that can prolong survival for a small but increasing number of patients with Dukes stage B or C disease, provided they are detected early, before symptoms develop. It is therefore

recommended that CEA is measured every 3 months for at least 3 years following surgery in patients with Dukes stage B or C disease who would be candidates for liver resection. Measurement of CEA following liver resection provides a helpful indication of its success.

Its measurement is also recommended during chemotherapy for metastatic disease, but care in interpretation is required because CEA concentrations may be affected by factors other than tumor progression (e.g., liver damage). CEA-defined responses agree well with radiologic responses (the “gold standard”) in greater than 90% of cases, enabling the conclusion that use of CEA is as accurate as CT imaging for assessing the response of colorectal cancer liver metastases to chemotherapy.

Monitoring of colorectal cancer outside a clinical trial should be undertaken only if it is likely to benefit the patient. CEA concentrations in individual patients should be monitored using the same method because results obtained in two methods may not be the same. If a change of method is unavoidable, re-baselining may be necessary, as described previously. Coordination of follow-up monitoring should ideally be supported by an automated computer system.

Gastric Cancer

Gastric cancer is relatively rare, although it is the second most common gastrointestinal cancer worldwide. Approximately 25,000 new cases are diagnosed in the United States each year, more than 60% of which will have already spread to regional lymph nodes or metastasized. Survival is closely related to stage at diagnosis, with 5-year survival approximately 65% for localized disease and less than 5% for patients with distant metastases.

Tumor Markers Used in the Management of Gastric Cancer

Although CEA and CA 19-9 are increased in 20% to 50% of patients with advanced disease and AFP in 20% to 25%, these markers are raised in less than 20% of patients with early-stage disease and consequently cannot be used for screening or diagnosis of gastric cancer. Measurement of serum CEA or CA 19-9 may provide early indication of recurrence in a proportion of patients, but their use is not recommended because there is currently no evidence that this improves clinical outcome.

This may change with availability of more effective systemic treatment because 10% to 25% of patients overexpress HER2. Because patients with advanced HER2-positive gastric tumors benefit from treatment with the anti-HER2 antibody, if such patients are being considered for systemic therapy, HER2 should be measured.

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) present predominantly in middle-aged and older individuals and, although rare, are the most common mesenchymal tumors of the gastrointestinal tract, occurring in the stomach, small bowel,

large bowel, esophagus, or omentum. Increased awareness of this tumor type since the 1990s has led to appropriate pathologic diagnoses, with incidence estimated between 0.68 and 1.5 per 100,000 population in several Western countries.

Tumor Markers Used in the Management of Gastrointestinal Stromal Tumor

Molecularly, greater than 95% of GISTs are characterized by the presence of KIT protein (also known as CD117 antigen), whose measurement in serum is recommended by a number of expert groups. Mutations in the *KIT* gene occur in approximately 80% to 85% of all cases, and mutations in the homologous *PDGFRA* gene are found in 5% to 10% of GIST patients.

The outcome for patients with GISTs has been dramatically improved in recent years with the advent of tyrosine kinase inhibitors, which block *KIT* and *PDGFRA*, as well as BCR-ABL. Response to these drugs depends on the mutational status of the *KIT* gene with patients, so *KIT* and *PDGFRA* mutational analysis is also recommended prior to prescribing imatinib to patients with GISTs.

Germ Cell Tumors

Although representing only 1% of all male tumors, GCTs are the solid tumor most frequently diagnosed in men between the age of 20 and 34 years and account for approximately 95% of malignant tumors arising in the testes. They also occur elsewhere, particularly along the “midline” (i.e., the mediastinum, retroperitoneum, or perineal gland). The incidence of GCTs has increased over the past few decades, with 8430 new cases predicted in the United States in 2015. Risk factors include positive family history, cryptorchidism, testicular dysgenesis, Klinefelter syndrome, and a prior history of GCT.

Although GCTs are usually aggressive, they respond well to treatment with surgery and, where appropriate, adjuvant chemotherapy and/or radiotherapy. Anticipated 5-year survival rates are now 98% in the United States, although 5-year survival rates in patients presenting with advanced disease due to delay in diagnosis are only 50% to 60%. There are well-established national and international guidelines relating to the management of patients with GCTs. Treatment in specialist centers is advantageous, and all patients should be discussed at multidisciplinary team meetings at which a clinical biochemist is present.

Tumor Markers Used in the Management of Germ Cell Tumors

Measurements of hCG, AFP, and LDH are integral to the management of patients with GCTs. Tumor marker results should be reviewed together with histologic immunostaining and radiologic results and any inconsistencies noted when treatment decisions are considered.

Screening. The low prevalence of GCTs in the general population, together with the relatively low sensitivity and specificity of AFP, hCG, and LDH, preclude the use of tumor markers in screening.

Diagnosis. Although rare, the possibility of a GCT should be considered in any patient with a poorly defined epithelial malignancy, especially young individuals with midline masses. Plasma or serum AFP and hCG should be measured in any male with a suspicious lump in the testes and in any patient with malignancy of unknown origin. Hyperthyroidism may be a presenting feature if the hCG concentration is very high because hCG shares structural similarities with thyroid-stimulating hormone (TSH). Patients with clinical findings consistent with GCTs (e.g., testicular lump, lung metastases, and/or abdominal mass) and markedly increased serum concentrations of AFP and/or hCG should be urgently discussed with physicians at the regional cancer center. Referral for immediate chemotherapy may be appropriate before later surgery to remove residual tumor.

Measurement of serum tumor markers is essential for the differential diagnosis of GCTs because treatment differs according to whether the GCT is seminomatous, nonseminomatous (NSGCT) (with yolk sac elements), or a combined tumor with both seminomatous and nonseminomatous elements. Serum or plasma concentrations of AFP and/or hCG are increased in 80% to 85% of men with NSGCT, whereas less than 25% of those with seminomas have raised hCG and none have raised AFP. Nonseminomas are more clinically aggressive, so tumors with both elements are managed as for nonseminomas. Increased AFP precludes a diagnosis of seminoma. Marker measurements can sometimes modify histopathologic diagnoses. Increased AFP in a patient diagnosed with seminoma suggests that the AFP may not be related to the tumor (e.g., may be of liver origin) or that yolk sac elements were overlooked.

hCG and AFP should be measured before surgery for a suspected GCT to allow the rate of fall of the markers to be monitored post treatment.

As for all tumor markers, it is important to remember that concentrations within the reference interval do not necessarily exclude malignancy. Only a small proportion of seminomas or dysgerminomas (the female equivalent of seminomas) produce hCG and up to 25% of NSGCTs do not produce AFP or hCG.

As for other oncology applications, the hCG method used should recognize both intact hCG and its free β -subunit (hCG β). hCG increases have to be interpreted with caution because hypogonadism and marijuana use may cause benign serum increases. Some immunoassay methods for hCG may be vulnerable to interference from **heterophilic antibodies** and **high-dose “hooking”** is always a possibility (see Interferences discussion earlier). Both AFP and hCG can be increased in nonmalignant diseases and other malignancies, and both are significantly raised in pregnancy.

Prognosis. The lowest tumor marker concentration reached post surgery, the primary tumor site, and the sites of metastatic disease all contribute to the prognostic classification of GCTs using criteria established by the International Germ Cell Cancer Collaborative Group. Treatment depends on whether the tumor is classified as having good, intermediate, or poor prognosis.

Monitoring. Provided disease is confined to the testis or ovary, serum AFP and/or hCG should decline to normal with respective apparent half-lives of 5 to 6 days for AFP and 1 to 2 days for hCG. Fig. 20.3 shows the decrease in AFP observed in a patient with widespread metastatic disease who had a complete radiologic and marker response to chemotherapy. The equation used to calculate the apparent half-life ($t_{1/2}$) of the tumor marker is

$$t_{1/2} = \frac{-0.3t}{\log_{10} \frac{[M]_T}{[M]_{T_0}}}$$

Fig. 20.3 Tumor marker responses in a patient with widespread metastatic disease who had a complete radiologic and marker response to chemotherapy. *AFP*, α -Fetoprotein; *hCG*, human chorionic gonadotropin.

where $[M]_T$ and $[M]_{T_0}$ are tumor marker concentrations at time T and T_0 , respectively, and t is the difference in days between T and T_0 .

Further treatment with chemotherapy or radiation is required if AFP and/or hCG remains increased following surgery or if imaging identifies residual or metastatic disease.

Long-Term Surveillance. Following treatment, tumor markers should be measured regularly following defined clinical protocols, which depend on prognostic category and treatment. Clearly any significant increases in tumor markers must be reported immediately to the relevant clinical team. The importance of careful monitoring of tumor markers is illustrated in Fig. 20.4. After an initially very good response to a number of different chemotherapy agents, the patient required surgery, further chemotherapy, and ultimately a successful bone marrow transplant.

Gestational Trophoblastic Disease

Gestational trophoblastic disease (GTD) is a rare and previously fatal disease of pregnancy that develops in the trophoblast cells that surround the embryo immediately after conception. They may occur following a molar pregnancy, a nonmolar pregnancy, or a live birth. The possibility of GTD should be considered in any woman who develops hyperemesis, excessive uterine enlargement, or persistent irregular vaginal bleeding after a pregnancy or a failed pregnancy. A urine hCG pregnancy test should be performed in any woman presenting with such symptoms. Diagnosis

Fig. 20.4 Tumor marker monitoring of a patient who required a number of chemotherapy treatments prior to surgery, further chemotherapy and a bone marrow transplant. *AFP*, α -Fetoprotein; *hCG*, human chorionic gonadotropin.

requires histologic examination of the products of conception following surgical evacuation. If there is any evidence of persistence of GTD, which is most commonly defined as a persistent increase of serum hCG, the condition is referred to as GTN.

Characteristics of the main forms of GTD are briefly described next.

Hydatidiform Moles

Hydatidiform moles (“molar pregnancies”) are the most common form of GTD and are nonmalignant. They may develop when a sperm fertilizes an “empty” egg containing no nucleus (a “complete” mole) or when two sperm fertilize a normal egg (“partial” mole). Fetal tissue is not present in complete moles. Following surgical removal, few patients with a partial mole require further treatment, and these moles rarely become malignant.

Invasive Moles

Following surgical removal of a complete mole, approximately 20% of women develop invasive moles. The tumor metastasizes to other sites (most often lung) in approximately 15% of patients. The risk of metastasis is increased if more than 4 months elapse between cessation of periods and treatment, if the uterus has become very large, if the woman is older than 39 years, or if she has had a previous GTD.

Choriocarcinoma

Choriocarcinoma most frequently develops from a complete hydatidiform mole but can occur after normal pregnancy or after early fetal loss in pregnancy. Metastasis to distant organs is more likely than for invasive moles but can be treated highly effectively with chemotherapy.

Placental Site Trophoblastic Tumors

These rare forms of GTD develop if the placenta remains attached to the uterus after a normal pregnancy or abortion. The tumors must be completely removed surgically and are not sensitive to chemotherapy, but they do not usually metastasize.

Tumor Markers in Gestational Trophoblastic Disease

Successful clinical management of GTD depends on accurate measurement of hCG, which has approximately 99% specificity and sensitivity for this disease in the clinical setting described previously, achieving almost ideal tumor marker performance in this application. Measurement of hCG using a method that recognizes both hCG and hCG β is essential.

Human Chorionic Gonadotropin in Screening for Gestational Trophoblastic Disease

Screening of women at high risk of developing GTD (i.e., women who have had a partial or complete hydatidiform mole in a previous pregnancy) is conveniently performed by measuring hCG in urine collected by the patient in her own home and sent by mail to a central screening center. In the United Kingdom, there is a well-established registration system that enables lifetime follow-up, which is recommended because the disease can occur years after the affected

pregnancy. Three specialist centers provide hCG testing in urine, with all patients referred for treatment to a specialist unit in London. Costs of the program are relatively low compared with the social cost avoided per life saved.

Human Chorionic Gonadotropin as an Aid to Diagnosis of Gestational Trophoblastic Disease. Definitive diagnosis requires histologic examination of the products of conception, but hCG serum measurements may be helpful in diagnosing molar pregnancies because values greater than two multiples of the median for the gestational date are suggestive of GTD.

Human Chorionic Gonadotropin in Prognosis. Prognosis is assessed according to the International Federation of Gynecology and Oncology staging system for GTN, which includes pretreatment hCG concentration as one of eight prognostic factors used for scoring. Women at high risk of recurrence are treated with multiagent chemotherapy until the hCG concentration returns to normal and then for a further 6 weeks.

Monitoring

Posttreatment monitoring is essential in the follow-up of molar pregnancy and involves serial measurements of hCG in either blood or urine. A urinary hCG pregnancy test should be performed 3 weeks after medical management of failed pregnancy if products of conception are not sent for histologic examination. Following a diagnosis of GTD and surgical evacuation, if the hCG concentration has reverted to normal within 56 days, then follow-up will be for 6 months from the date of uterine evacuation. If hCG has not reverted to normal within 56 days, then follow-up will be for 6 months from normalization of the hCG concentration. In the United Kingdom, women who have had GTD in a previous pregnancy are requested to notify the screening center following any future pregnancies, whatever the outcome of the new pregnancy. hCG concentrations are then checked 6 to 8 weeks after the end of that pregnancy to exclude disease recurrence.

Hepatocellular Carcinoma (Primary Liver Cancer)

The 11th most commonly diagnosed cancer in the United States, HCC is the sixth most common cause of cancer death. Worldwide, however, HCC is the second leading cause of cancer death, with an incidence that has increased exponentially in recent decades. Asian countries account for approximately 78% of the 600,000 new cases of HCC reported annually. Risk factors are generally the same as those for liver cirrhosis. In China, Southeast Asia, and sub-Saharan Africa the major causative factors are chronic infection with hepatitis B virus (HBV) and ingestion of food contaminated with aflatoxin B, a fungal toxin that is genotoxic and carcinogenic. Nonviral causes associated with increased risk for HCC are more common in Western countries and include alcoholic cirrhosis, Wilson disease, and stage IV primary biliary cirrhosis. The increasing incidence of HCC in Europe probably reflects the increased frequency of chronic hepatitis C infection and liver cirrhosis, both of which are strong predisposing factors for HCC.

Signs and symptoms of HCC at presentation may include jaundice, hepatomegaly, ascites, peripheral edema, pruritus,

bleeding esophageal varices, and right upper quadrant pain. CT, MRI, and/or biopsy are required for diagnosis. Depending on imaging results, biopsy confirmation of a diagnosis may not be required for liver nodules greater than 1 cm in size.

Potentially curative treatment options include liver transplantation (for which only approximately 5% of patients are suitable), surgical resection (which requires very good liver function and has a recurrence rate of 50% to 60% after 5 years), ablative therapy (with alcohol, radiofrequency, and/or microwaves), chemoembolization, and chemotherapy. Eligibility for these treatments depends on diagnosing early stage disease, which is often asymptomatic. In developed countries, only 30% to 40% of HCC patients are diagnosed early enough for curative treatment.

Tumor Markers for Hepatocellular Carcinoma

AFP is the most clinically useful tumor marker for HCC. AFP concentrations may range from within the reference interval to as high as $10 \times 10^6 \mu\text{g/L}$ ($8.3 \times 10^6 \text{ kU/L}$) but may not be increased in up to 20% of untreated patients with HCC, especially in early-stage disease. AFP concentrations may be transiently raised in regenerating liver nodules during recovery from viral hepatitis, as well as in some benign conditions.

Screening for Hepatocellular Carcinoma in High-Risk Groups Using α -Fetoprotein

There is increasing evidence that early detection of HCC through well-organized screening of high-risk populations with abdominal ultrasound and 3- or 6-monthly AFP measurements can improve clinical outcome. Studies suggest that serial AFP testing more accurately identifies those patients with hepatitis C virus (HCV) and/or advanced fibrosis or cirrhosis who are most likely to develop HCC. If serum AFP is rising or if a liver mass nodule is identified on ultrasound, the NCCN recommends additional CT or MRI imaging. According to the NACB, AFP concentrations greater than or equal to $20 \mu\text{g/L}$ (i.e., $\geq 17 \text{ kU/L}$) and rising should prompt further investigation even if ultrasound is negative.

α -Fetoprotein as an Aid to Diagnosis. The same caveats that apply to use of AFP for screening apply to its use as an aid to diagnosis. In general, ultrasound scan (USS)-detected nodules of less than 1 cm should be monitored at 3-monthly intervals but those of 1 to 2 cm in cirrhotic livers should be investigated by two imaging modalities (e.g., CT and MRI) and treated as HCC if imaging results are consistent with this. For liver lesions greater than 2 cm in size where USS is typical of HCC and AFP is greater than $200 \mu\text{g/L}$ (i.e., $\sim 170 \text{ kU/L}$) and USS, a diagnosis of HCC can be made without biopsy. If no mass is detected, AFP testing and liver imaging should be continued every 3 months.

α -Fetoprotein in Prognosis. AFP concentrations may provide prognostic information in untreated HCC patients and in those being considered for liver resection or transplantation, with high concentrations generally associated with poor prognosis. Preoperative AFP decision limits ranging from 200 to $1000 \mu\text{g/L}$ (i.e., ~ 170 to 830 kU/L) have been suggested to predict outcome after liver transplantation, but there is no

international agreement about the decision concentration. In the United Kingdom, current National Health Service (NHS) Blood and Transplant guidelines state that patients with serum AFP greater than $1200 \mu\text{g/L}$ (i.e., $>1000 \text{ kU/L}$) should be deselected from eligibility for transplant.

α -Fetoprotein in Posttreatment Monitoring. Measurement of AFP at follow-up visits is recommended to monitor disease status after liver resection or liver transplantation, for detection of recurrence or after ablative therapies and/or during palliative treatment. This reflects the general consensus that earlier identification of disease may enable alternative treatments to be instituted or patients entered in a clinical trial. Current practice suggests monitoring patients with AFP every 3 months for 2 years and then every 6 to 12 months. Rising AFP concentrations should be confirmed with a repeat specimen within 3 months. Reevaluation, including AFP measurement, should be instituted earlier if there is clinical suspicion of disease recurrence.

Lung Cancer

Lung cancer has been the most common cancer and cause of cancer death worldwide for several decades, with an estimated 1.8 million new cases in 2012, 58% of which occurred in less developed regions. It is also the most common cause of death from cancer worldwide, accounting for nearly 20% of all cancer deaths. Survival rates depend strongly on tumor stage at diagnosis. Trends in incidence and mortality generally reflect smoking habits and/or exposure to other environmental or occupational carcinogens.

Early symptoms are nonspecific and include dyspnea, cough, and thoracic pain, with hemoptysis often indicating advanced disease. Investigations for suspected lung cancer include CT and/or MRI, bronchoscopy, and biopsy. Histologic differentiation and staging of lung cancer is essential because the two major histologic types have different clinical behaviors and sensitivity to chemotherapy and radiotherapy.

Approximately 75% to 85% of lung cancers are primarily NSCLC and require surgery as first-line treatment, with subsequent adjuvant radiotherapy and/or chemotherapy if appropriate. Several new biologic therapies are also available, targeting EGFR or vascular endothelial growth factor (VEGF). Small cell lung cancers (SCLCs) account for the other 15% to 25%. These often have neuroendocrine components and respond to chemotherapy and/or radiotherapy. They are aggressive tumors that double rapidly and metastasize early.

Tumor Markers in the Management of Lung Cancer

The serum tumor markers most frequently associated with SCLC are neuron-specific enolase (NSE) and progastrin-releasing peptide (ProGRP), whereas Cyfra 21-1 and CEA are primarily associated with NSCLC. SCCA may be raised in the subset of NSCLC patients with squamous cell carcinoma.

Screening and as Aids to Diagnosis. No serum tumor markers are sufficiently sensitive or specific, singly or in combination, for use in screening for lung cancer, even in high-risk groups such as smokers.

In patients in whom inoperable lung cancer is suspected but for whom histology is not available, clearly increased serum NSE and/or ProGRP support a diagnosis of SCLC and clearly raised serum SCCA concentrations are consistent with squamous cell cancer.

Prognosis. Measurements of Cyfra 21-1, CEA, and/or LDH may provide prognostic information for NSCLC, and NSE and LDH can be used similarly in SCLC.

Therapy Prediction. Serum tumor markers cannot be used to predict therapy response in lung cancer patients. However, as for colorectal cancer, anti-EGFR therapy is available for treatment of patients with NSCLC.

In agreement with other groups, ASCO recommends EGFR and ALK testing for all patients with lung adenocarcinoma or mixed lung cancer (both primary and metastatic) with a component of adenocarcinoma.

Monitoring. Monitoring of lung cancer patients with serum tumor markers is controversial in view of the often aggressive nature of the disease. Serial determinations following surgery may provide an indication of the completeness of tumor removal and an early indication of subsequent recurrence. The latter is likely to benefit the patient only if alternative treatment is available, and there is as yet no evidence to suggest that monitoring improves outcomes.

Melanoma

Melanoma is a skin cancer that can occur anywhere on the body but is most common in skin that is frequently exposed to sunlight. The incidence of melanoma has steadily increased over the past 30 years. Signs of melanoma include changes in the appearance of moles or pigmented areas of the skin. Surgery is curative in early-stage disease, but the prognosis is poor in metastatic disease.

Tumor Markers Used in the Management of Melanoma

Diagnosing malignant melanoma in pathologic specimens involves staining with antibodies to S100, a family of multifunctional proteins with regulatory roles in a number of cellular processes. S100 is increased in serum in patients with malignant melanoma, but its clinical utility has yet to be established and it lacks sensitivity in early disease. Rising concentrations are specific and sensitive for progression in patients with advanced disease, but its measurement is appropriate only if further treatment options are available. Although very nonspecific, LDH can be used to monitor patients with melanoma and may have prognostic value in advanced disease.

Therapy Prediction. The *BRAF*-mutated protein can be selectively targeted by a number of inhibitors that are very effective in patients with *BRAF* mutation-positive advanced melanomas. Commercially available predictive biomarker assays have now been cleared by the FDA for the identification of patients with metastatic or unresectable melanoma who are likely to benefit from these drugs.

Neonatal and Pediatric Tumors

In children younger than 15 years, cancer is the second leading cause of death, but advances in treatment mean that more

than 70% of children diagnosed with cancer are now cured. Tumor markers can contribute significantly to the management of childhood neuroblastomas, malignant hepatic tumors, and GCTs. The general principles are the same as for adults with some additional caveats.

Tumor Markers Used in the Management of Childhood Malignancies

AFP and hCG are the tumor markers most frequently used in childhood malignancies. AFP is markedly increased at birth and then declines steadily to adult concentrations by 6 to 12 months. Age-related reference intervals are therefore essential. AFP is higher in preterm infants and may remain increased for longer in children with delayed development. Serial measurements are often more useful than isolated results, particularly in neonates, in whom acute hepatocellular damage may result in marked increases in AFP concentrations.

Additional care must be taken to avoid reporting results that are inappropriately low due to high-dose “hooking” because tumor marker concentrations may be very high in some childhood cancers. Considerable care is also required to ensure that dilutions of serum are made and recorded correctly. Because AFP and hCG requests for young children are relatively infrequent, it is highly desirable that all such samples are routinely assayed at more than one dilution.

Childhood Germ Cell Tumors

Measurement of AFP and hCG is mandatory because either or both are frequently increased at the time of diagnosis. Yolk sac tumors are the most common pure malignant GCTs in childhood. Dysgerminomas are the most common pure malignant GCT occurring in the ovary and central nervous system in girls, who may present with precocious puberty.

Hepatoblastoma

Hepatoblastoma and HCC are the most frequent malignant hepatic tumors in childhood and differential diagnosis is essential. More than 80% of children with hepatoblastoma and approximately 50% of those with HCC have tumors that produce AFP, often at extremely high concentrations (e.g., 1.2×10^6 $\mu\text{g/L}$ [1.0×10^6 kU/L]). Children with hepatoblastomas that secrete hCG may develop precocious puberty. Complete surgical resection is the treatment of choice for hepatoblastomas and HCC, with adjuvant chemotherapy also important for hepatoblastomas.

Neuroblastoma

Neuroblastomas are malignant embryonal tumors that may exhibit extremely malignant behavior or may regress spontaneously. They account for 8% to 10% of childhood cancers, with approximately 80% of cases occurring in children younger than 4 years. Treatment includes surgery, chemotherapy, and radiotherapy. The diagnosis can be confirmed and the success of treatment monitored by measuring urinary catecholamines, which are increased in greater than 90% of cases.

Ovarian Cancer

Ovarian cancer is relatively rare (approximately 12.1 new cases per 100,000 women per year in the United States) and most frequently diagnosed in women aged between 55 and 64 years old. Five-year survival rates are greater than 90% for women diagnosed with disease confined to the ovary but approximately 28% for women with advanced disease at diagnosis. Early detection is difficult due in part to the relative rarity and heterogeneity of the disease, and as many as 30% of women with ovarian cancer may present for the first time at the emergency department.

Most malignant ovarian tumors (80% to 85%) are surface epithelial carcinomas that occur in five distinct histologic subtypes, predominantly serous. When evaluating the clinical utility of tumor markers in ovarian cancer, the different clinical behavior of the different subtypes must be considered.

GCTs account for approximately 15% of malignant ovarian tumors (see Germ Cell section) or sex cord stromal tumors, two-thirds of which are granulosa cell tumors.

Tumor Markers Used in the Management of Ovarian Cancer

CA 125 is the most widely used serum tumor marker for all epithelial ovarian cancers but is most sensitive for serous adenocarcinomas. CA 125 is raised in many nonmalignant conditions (Table 20.7), so careful interpretation of results in the clinical context is essential. Occasional and sometimes transiently raised concentrations of CA 125 greater than 5000 kU/L may be seen in patients with nonmalignant ascites, and CA 125 is increased in other malignancies, particularly adenocarcinomas. Some methods are vulnerable to interference, particularly from heterophilic antibodies.

Human epididymal protein 4 (HE4), a member of the “four disulfide core” family of proteinase inhibitors, has recently emerged as a promising serum tumor marker that could potentially complement measurement of CA 125 in ovarian cancer patients. Serum HE4 is less sensitive than CA 125 for detecting early-stage ovarian cancers among asymptomatic women but has better sensitivity and specificity for differentiating malignant from nonmalignant pelvic masses, especially in premenopausal patients. HE4 is not increased during menstruation but significantly increases in renal failure and with advancing age.

The serum markers of choice for ovarian GCT are AFP, hCG, and LDH, whereas for granulosa cell tumors, inhibin is the appropriate tumor marker. An inhibin method that detects all forms of inhibin, including inhibin A, inhibin B, and pro- α C, is required.

Screening for Ovarian Cancer. A reliable screening test for early ovarian cancer could make a major difference to outcome because most patients with advanced disease die of it. Assuming a disease prevalence of 40 per 100,000 in women older than 50 years, very high specificity (99.7%) is required to achieve an acceptable positive predictive value of 10% for ovarian cancer. The feasibility of screening women older than 50 years using CA 125 and ultrasound has been investigated extensively in several large major randomized controlled trials, with conflicting conclusions.

In the United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), CA 125 was measured annually for 202,638 postmenopausal women. The number of screen-detected primary invasive epithelial ovarian cancers was double the number that would have been detected using a fixed cutoff, supporting the use of velocity-based algorithms in cancer screening strategies that use blood biomarkers. Survival data from this trial are awaited.

Women who are *BRCA1* or *BRCA2* mutation carriers are at high risk because 1.0% to 2.5% or 0.4% to 0.8%, respectively, will develop ovarian cancer each year. The American College of Obstetricians and Gynecologists recommends risk-reducing salpingo-oophorectomy (i.e., total removal of the ovaries and fallopian tubes) by age 40 years for these women. For women declining this operation, screening with transvaginal ultrasound and/or CA 125 can be offered at the clinician's discretion. Outcome data from the United Kingdom Familial Ovarian Cancer Screen Study (UK FOCSS) and from a prospective longitudinal CA 125 screening study of high-risk women by the Gynecologic Oncology Group are awaited.

Diagnosis. CA 125 measurement in isolation is not recommended for diagnosis due to its low sensitivity and specificity for ovarian cancer. A level within the reference interval does not necessarily exclude ovarian cancer, and an increased concentration does not necessarily indicate it, particularly in premenopausal women. Nevertheless, extremely high CA 125 values may be helpful in evaluating premenopausal women provided other potential causes are excluded.

In postmenopausal women, CA 125 measurement can help in differentiating malignant from nonmalignant pelvic masses using well-established RMI algorithms, which incorporate ultrasound, menopausal status, and CA 125. At an RMI cutoff value of 200, the positive predictive value for malignancy is approximately 80%.

Women with ovarian cancer may develop nonspecific symptoms several months before diagnosis of early-stage disease. Reflecting this, UK National Institute for Health and Clinical Excellence (NICE) guidelines recommend that serum CA 125 be measured in women presenting with persistent, frequent (>12 times a month), and continuous symptoms including abdominal bloating or distension, early satiety and/or loss of appetite, pelvic or abdominal pain, and/or increased urinary urgency and/or frequency. If CA 125 is greater than or equal to 35 kU/L, an USS of the abdomen is arranged and the RMI calculated. Women with RMI greater than 250 are referred urgently to a specialist team. Audit will be required to assess the cost effectiveness of this approach.

Prognosis. Higher preoperative CA 125 concentrations are generally associated with worse prognosis. Five-year survival rates in patients with a preoperative CA 125 concentration greater than 65 kU/L have been found to be significantly lower than those for patients with CA 125 less than 65 kU/L. CA125 values greater than 500 kU/L may predict the occurrence of difficult or complex surgery, potentially aiding treatment planning.

Following primary treatment with surgery and/or chemotherapy, the rate and extent of fall of CA 125 during the initial two cycles of platinum-based chemotherapy generally reflect prognosis. Factors influencing CA 125 concentrations post surgery must be taken into account to minimize the risk of misinterpreting results.

Monitoring. Criteria used to evaluate changes in CA 125 during treatment and follow-up are included in the Response Evaluation Criteria in Solid Tumors (RECIST). A CA 125 response is defined as a 50% decrease from the pretreatment concentration provided the decrease is maintained for at least 28 days. The RECIST criteria enable objective assessment of response, which can influence decisions to continue effective treatment or change ineffective treatment.

Following completion of treatment, standard practice has been to monitor complete remission and then potential increases in CA 125 prior to clinical signs of relapse (median lead time approximately 4 to 5 months). The UK-based Medical Research Council/European Organisation for Research and Treatment of Cancer (MRC-EORTC) conducted a randomized trial to evaluate the utility for such monitoring of CA 125. Results indicated that early intervention based on CA 125 conferred no survival advantage but resulted in earlier deterioration in quality of life. It was concluded that the value of routine measurement of CA 125 in the follow-up of patients with ovarian cancer who attain a complete response after first-line treatment is not proven and that these patients should be told that routine CA 125 monitoring is not necessary until or unless they are worried or develop any signs suspicious of tumor relapse.

Results of the MRC-EORTC trial challenge existing assumptions and have generated considerable debate, with a number of aspects of the study questioned. The European Society of Gynaecological Oncology (ESGO) issued a consensus statement advising that the use of CA 125 should not be universally abandoned in the routine follow-up of all patients with ovarian cancer. Their recommendations are broadly in line with those of the MRC-EORTC trial coordinator and of other groups, most of which recommend that the pros and cons of monitoring with CA 125 should be objectively discussed with the patient.

Pancreatic Cancer

Pancreatic cancer is the 12th most common cancer in the United States, representing 3% of all new cancer cases and is the fourth leading cause of cancer death. Most patients with pancreatic cancer present with symptoms that may include jaundice, weight loss, abdominal pain, nausea or vomiting, and/or pruritus. Only 9% are diagnosed when the tumor is still localized and resectable.

Tumor Markers Used in the Management of Pancreatic Cancer

The most clinically useful serum tumor marker for pancreatic cancer is CA 19-9, a sialylated Lewis a antigen (Le^a) commonly produced in pancreatic and hepatobiliary disease but also increased in many other conditions (Table 20.7). CA 19-9

is undetectable and therefore uninformative in the 5% to 10% of the general population who are Le^a negative.

Clinical Applications of CA 19-9 in Pancreatic Cancer

Screening and Diagnosis. The low positive predictive value of CA 19-9 means it cannot be used in screening, but in symptomatic patients it can contribute to diagnosis. It should be measured only in patients in whom pancreatic cancer is suspected and with the usual caveats that a result within the reference interval does not exclude pancreatic malignancy and vice versa. CA 19-9 may be increased in biliary infection (cholangitis), inflammation, or biliary obstruction, so it is best measured after complete biliary decompression and when bilirubin is normal. It is frequently increased in patients with biliary obstruction due to benign pancreatobiliary and other conditions.

Prognosis and Therapy Prediction. Preoperative CA 19-9 concentrations correlate with staging and disease burden, so they can complement information from imaging, laparoscopy, and biopsy when assessing whether a pancreatic tumor is resectable. In patients without biliary obstruction, a high CA 19-9 concentration can be used as an indication for staging laparoscopy, with concentrations greater than 130 kU/L strongly associated with subradiographic unresectable disease. Low postoperative CA 19-9 concentrations at 3 months and before adjuvant chemotherapy are independently prognostic, with normalization of CA 19-9 following neoadjuvant therapy associated with longer median survival. Postoperative CA 19-9 concentrations may also help to predict the benefit of adjuvant therapy.

Monitoring. Rising CA 19-9 concentrations suggest progression and can be used, together with radiographic and clinical data, to influence decisions to initiate palliative treatment in a patient whose disease progresses after surgery or to change (or discontinue) chemotherapy in patients progressing during treatment. Obtaining a CA 19-9 measurement immediately before each therapeutic intervention is essential to have a baseline with which to compare subsequent results. ASCO does not recommend the routine use of serum CA 19-9 alone to monitor response to treatment but states that in advanced disease CA 19-9 can be measured at the start of treatment for locally advanced metastatic disease and every 1 to 3 months during active treatment. An increase may indicate progression and should prompt confirmation with other modalities.

It is particularly important that the same CA 19-9 method be used for serial monitoring because results are not interchangeable between methods.

Prostate Cancer

Prostate cancer is most frequently diagnosed in men aged 65 to 74 years old. It accounts for approximately 13.3% of all new cancer cases in the United States in 2015 but for only 4.7% of all cancer deaths. Although many more men with prostate cancer die with, rather than of, their cancer (by the age of 80 years, autopsy studies show that approximately 80% of men have some cancer cells in their prostate), some prostate

cancers are lethal. Developing a reliable and noninvasive means of differentiating aggressive cancers from indolent cancers remains a major challenge.

Common symptoms at presentation include frequency, urgency, nocturia, dysuria, acute retention, prostatic enlargement, back pain, weight loss, and anemia. The first six of these are also associated with benign prostatic hyperplasia (BPH), a nonmalignant condition reflecting increased prostate size with advancing age. The last three symptoms tend to be symptomatic of more advanced prostate cancer.

Treatment options for early-stage disease include curative surgery (prostatectomy), brachytherapy, and radiotherapy, and “active surveillance” without intervention is also a realistic option. In advanced metastatic disease, endocrine (antandrogen) therapy is effective because prostate cancers are dependent on testosterone. However, many advanced cancers eventually no longer respond to traditional androgen-reducing treatments and other treatment options, including chemotherapy, are required.

Widespread measurement of serum PSA, which can identify potential prostatic disease in both asymptomatic and symptomatic patients, informs decisions to proceed to prostatic biopsy, and probably accounts for an apparent increased incidence of prostate cancer. However, many of the cancers identified are indolent and such overdiagnosis is a major issue for health systems.

Tumor Markers Used in the Management of Prostate Cancer

Prostate-Specific Antigen. Optimal treatment of patients with prostate cancer relies on PSA measurements. Unlike many other tumor markers, PSA is essentially organ-specific. However, PSA is not cancer-specific because increased serum concentrations occur in men with benign prostatic disease and/or urinary tract infections and following intervention involving the prostate. Prostatic biopsy is therefore required for definitive diagnosis.

A member of the kallikrein serine protease family, 70% to 90% of immunoreactive PSA protein in blood is bound to protease inhibitors, primarily α_1 -antichymotrypsin (ACT). The remaining 10% to 30% of the immunoreactive protein circulates in a free or unbound form, thought to be biologically inactive and known as “free PSA.” Multiple forms of free PSA and its precursor forms exist in serum and have been proposed as new markers for prostate cancer. In clinical practice, methods measuring total PSA (i.e., free PSA and the PSA-ACT complex) are most often used.

Several strategies to improve the diagnostic accuracy of PSA with the primary aim of decreasing the number of unnecessary biopsies are described as follows.

Age-Related Reference Intervals. Prostate size can increase with age, particularly in men with BPH, and may be associated with increased serum PSA values. Historically, a single PSA reference interval of less than 4.0 $\mu\text{g/L}$ has been used. Higher PSA reference intervals in older men could decrease unnecessary biopsies (i.e., increase specificity), whereas lower reference intervals in younger

men could increase cancer detection (i.e., improve sensitivity). Race-specific reference ranges have similarly been suggested because PSA tends to be higher in some populations (e.g., African-Americans). The value of age- and/or race-related reference intervals is still unclear. The NHS Prostate Cancer Screening Management Programme recommends use of age-related reference intervals, but other groups make no recommendations regarding their routine use.

Percent-Free Prostate-Specific Antigen (“Free to Total” Ratio). The ratio of free to total PSA is lower in prostate cancer patients than in men with BPH and those without prostatic disease. Determination of the ratio may therefore enable better discrimination of prostatic cancer and BPH. Measurement of percent-free PSA is most informative when total PSA is between 3 or 4 and 10 $\mu\text{g/L}$. Although measurement of percent-free PSA has been shown to reduce the number of unnecessary biopsies by 25% to 40%, some cancers may be missed.

Preanalytical requirements for measurement of free PSA are more rigorous than for total PSA because its half-life in blood is much shorter than that of total PSA (approximately 2.5 hours compared with 3 to 4 days). Later addition of the test to a stored sample may therefore be inappropriate. Percent-free PSA must be determined using paired kits from the same supplier.

Prostate-Specific Antigen Density. PSA density potentially differentiates men with high serum PSA due to a large prostate from those with prostate cancer. PSA density is estimated by dividing serum PSA ($\mu\text{g/L}$) by prostate volume (cc) as determined by transrectal ultrasound (TRUS).

Some studies suggest that this improves PSA specificity in men with larger prostates and improves PSA sensitivity in men with smaller glands, but other studies have not confirmed this. PSA density is rarely used in clinical practice.

Prostate-Specific Antigen Velocity. PSA velocity (PSAV), the rate of change of PSA over time, has been suggested to reflect aggressiveness of prostate cancer, with higher rates of change associated with greater risk of prostate cancer death. There are a number of caveats to the use of PSAV, which is not useful in patients with PSA values greater than 10 $\mu\text{g/L}$.

Other Tumor Markers for Prostate Cancer

Tests that are not at present widely used in clinical practice include PCA3 (a noncoding, prostate tissue-specific RNA measured in urine), phi (a combination of total PSA, free PSA, and proPSA measured in serum), 4K score (a combination of free and total PSA, human kallikrein 2, and intact PSA measured in serum), and ConfirmMDx (a multiplex epigenetic assay).

Prostate-Specific Antigen in Screening for Prostate Cancer. Screening asymptomatic men for prostate cancer with PSA is highly controversial, primarily because its inability to differentiate aggressive and indolent prostate cancers can inevitably lead to overdiagnosis and overtreatment of some men.

The feasibility of screening with annual PSA measurements has been investigated in five trials that were the subject of a Cochrane systematic review. Three trials used methodology that was assessed as posing a high risk of bias. The two larger studies, the European Randomized Study of Screening for Prostate Cancer (ERSPC) and the US Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial, were both assessed as posing a low risk of bias but reported contradictory results.

The ERSPC study was the only one of the trials to report significant (21%) reduction of prostate cancer–specific mortality in a prespecified subgroup of men aged 55 to 69 years after 13 years of follow-up. After the same length of follow-up, the PLCO study found no evidence of a mortality benefit for organized annual screening as compared with opportunistic screening, which forms part of standard care. Coordinators of the ERSPC study concluded that the balance of benefit and harm in prostate cancer screening has not yet been adequately characterized. Authors of both studies agreed that population screening should not be implemented at present and that asymptomatic men requesting PSA measurement should be objectively informed of the risks of overdiagnosis and overtreatment and potential adverse side effects before undergoing the test.

Prostate-Specific Antigen as an Aid to Diagnosis of Prostate Cancer. Men with symptoms suggestive of prostate cancer should be offered a PSA test and a DRE before referral for specialist care. A PSA result within the reference interval does not necessarily exclude prostatic disease, and an increased PSA does not necessarily indicate malignancy. However, in general the higher the PSA result the greater the likelihood of prostate cancer, providing prostatitis, urinary tract infection, catheterization, and other possible confounding factors that may increase PSA have been excluded. Results above the upper limit of the reference interval but less than 10 $\mu\text{g/L}$ are considered to be within a “gray zone” where additional testing (e.g., percent free PSA) may be undertaken in some centers before proceeding to biopsy. A second specimen to confirm a raised PSA result is always desirable.

In general, diagnosis of prostate cancer requires biopsy and pathologic confirmation unless clinical suspicion of malignancy is high, there is evidence of bone metastases, and the PSA concentration is clearly increased (e.g., $>100 \mu\text{g/L}$). Prior to prostatic biopsy, the benefits and potential side effects should be discussed with the patient, and individual risk factors (e.g., age and ethnicity) and comorbidities carefully considered.

Prostate-Specific Antigen in Prognosis and Therapy Prediction of Prostate Cancer. In patients with immunohistochemically confirmed prostate cancer, treatment depends on whether the disease is confined to the prostate or has spread to other organs, so accurate pretreatment staging is crucial. The pretreatment serum PSA value correlates with the risk of extraprostatic extension and lymph node involvement and is an independent predictor of response to all forms of treatment. Predictive tables or method-specific nomograms are available that combine pretreatment PSA concentrations with information on clinical stage and the immunohistochemical

Gleason score, which assesses the degree of cellular differentiation in the prostate tissue examined and ranges from 2 in well-differentiated tumors to 10 in completely anaplastic tumors.

Such nomograms can provide a reasonable indication of whether disease is localized to the prostate and aid in predicting treatment outcome. For example, a patient with a PSA of less than 10 $\mu\text{g/L}$ and a Gleason score of less than or equal to 6 is unlikely to have metastatic disease so pelvic lymph node dissection may not be necessary, and treatment options will include radical prostatectomy, localized radiotherapy, or active surveillance as described previously.

Pretreatment PSA can contribute to assessment of the need for bone, CT, and/or MRI scans for staging asymptomatic men with localized prostate cancer. Bone scans are generally not necessary in patients with newly diagnosed prostate cancer who have a PSA less than 20.0 $\mu\text{g/L}$ unless history or clinical examination suggests bony involvement and/or if the patient has a Gleason score greater than 8. Similarly, CT is rarely positive when pretreatment PSA is less than 20.0 $\mu\text{g/L}$ unless disease is locally advanced or the Gleason score is greater than or equal to 8.

Following radical prostatectomy, PSA should decrease to and remain at undetectable concentrations, with measurable concentrations indicative of residual disease or possibly the presence of benign glands. An initial post-prostatectomy PSA value of greater than 0.2 $\mu\text{g/L}$ followed by a subsequent confirmatory value is likely to indicate residual disease or recurrence but may not indicate need for initiation of treatment because the median interval from PSA recurrence to cancer death is between 5 and 12 years.

PSA decreases more slowly after radiotherapy, rarely falling to less than 0.2 $\mu\text{g/L}$. However, the level should remain stable. Any rise in PSA value greater than or equal to 2.0 $\mu\text{g/L}$ predicts treatment failure with great sensitivity and specificity after radiotherapy with or without androgen deprivation.

Following hormonal therapy, a low PSA nadir can be linked to survival. Failure to achieve a PSA nadir of less than 4.0 $\mu\text{g/L}$ 7 months after initiation of therapy is associated with very poor prognosis (median survival approximately 1 year), whereas patients achieving a nadir of less than 0.2 $\mu\text{g/L}$ have relatively good prognosis (median survival >6 years).

Prostate-Specific Antigen in Monitoring of Prostate Cancer. Sustained increases in PSA after treatment provide objective evidence of disease progression, often months before other diagnostic procedures. Consistently rising PSA usually, although not always, indicates recurrence. Conversely, a stable PSA does not necessarily exclude progression if clinically suspected. An increase in PSA should always be confirmed, taking into account intraindividual biologic variation in PSA of up to 20% to 30% before concluding an increase is clinically significant. For patients in whom it can be calculated, the PSA doubling time can provide valuable information about the likely time to progression. Patients with a PSA doubling time greater than 15 months have a low likelihood of prostate cancer–specific mortality over a 10-year period. In some patients, knowledge of increasing PSA concentrations may have adverse psychological

consequences, and monitoring with PSA may be undesirable, particularly if effective alternative treatments are not available.

Testicular Cancer

GCTs account for more than 90% of testicular tumors in adults (see earlier). Leydig and Sertoli cell tumors develop in the stroma, the hormone-producing tissue of the testicles, and represent 4% of adult testicular tumors and 20% of childhood tumors. Leydig cell tumors normally produce androgens. They usually do not spread and can be cured by surgical removal. Those that do spread are usually resistant to both chemotherapy and radiation. Sertoli cell tumors are very similar and are also difficult to treat if they spread beyond the testes.

As for granulosa cell tumors of the ovary, the marker of choice for both Sertoli and Leydig cell tumors is inhibin and the same analytical requirements apply.

Thyroid Cancer

Thyroid cancers represent approximately 2% to 4% of cancers in all age groups, with women more than 3 times likely to be affected. There are four histologic types: papillary, follicular, and anaplastic thyroid cancer and medullary thyroid carcinoma (MTC). The diagnosis is often made when a patient presents to the thyroid clinic with a painless neck lump. Because the major differential diagnosis required is between benign and malignant thyroid nodules, the reader is referred to [Chapter 42](#), but use of the relevant tumor markers is described briefly here.

Tumor Markers Used in the Management of Thyroid Cancers

Papillary and follicular thyroid cancers are differentiated thyroid cancers and can be monitored post treatment by measuring serum thyroglobulin. A large complex glycoprotein synthesized by the follicular cells of the thyroid and stored in the colloid space, thyroglobulin is present in benign and malignant thyroid tissue. Its production is stimulated by TSH, either from the pituitary or by injection of recombinant human TSH. In patients with an intact thyroid, thyroglobulin reflects thyroid volume and injury and also TSH receptor stimulation. It should be undetectable in serum in the absence of thyroid cells.

MTC is a rare and challenging malignancy that often presents as a lump in the neck, with dysphagia or systemic effects such as diarrhea or flushing. The 10-year survival is approximately 75%, but patients may survive for many more years even with a significant tumor burden. Most appropriately managed in specialist centers, MTC has a hereditary component in approximately 25% of cases and can be associated with multiple endocrine neoplasia (MEN) 2B. Germline testing for the RET proto-oncogene distinguishes hereditary from sporadic MTC and should be offered to all patients with a family history consistent with MEN 2 or familial MTC. Prophylactic thyroidectomy may be indicated in children, and screening for other endocrine tumors (e.g., pheochromocytoma, pituitary, parathyroid) is essential. Calcitonin, a 32-amino acid polypeptide produced by the C cells of the thyroid is an excellent tumor marker for MTC. CEA is also a very good marker of tumor burden in MTC.

Screening, Diagnosis, and Prognosis. Serum thyroglobulin measurement is not helpful in screening for or diagnosis of thyroid cancer and has no value as a prognostic marker. Basal calcitonin measurements can contribute to the diagnosis of C-cell hyperplasia, and MTC and CEA should be measured preoperatively.

Monitoring. Thyroglobulin has an important role in monitoring patients with papillary or follicular thyroid cancer after treatment with surgery and/or radioiodine. Following either of these treatments, TSH is usually kept suppressed by adjusting the replacement dose of thyroxine to minimize the risk of stimulating the growth of any remaining thyroid cancer cells. If TSH is suppressed, serum thyroglobulin should be undetectable following complete ablation. A confirmed rise in thyroglobulin is consistent with recurrence.

Calcitonin and CEA should be measured before surgery and 6 weeks post surgery. Any increase should be confirmed with an early repeat determination using the same analytical method. Provided the concentrations fall to within reference limits following treatment, annual monitoring may be adequate after the first year.

Analytical and Reporting Requirements for Thyroglobulin. There are several potential pitfalls in thyroglobulin measurement. Analytically, RIA and immunometric methods for thyroglobulin are vulnerable to interference from anti-thyroglobulin autoantibodies that may be present in some patient sera. Results obtained may be falsely low or falsely high, with immunometric methods being particularly prone to giving falsely low results. Appropriate cautions should be added to reports.

Cancers of Unknown Primary

When cancer is found in one or more metastatic sites but the primary site of origin cannot be determined, the diagnosis made is of cancer of unknown primary or occult primary cancer. Such cancers account for 2% to 3% of all new cancer diagnoses, with approximately 31,000 cases diagnosed per year in the United States. Symptoms vary according to the sites of metastases and may include swollen lymph nodes, abdominal mass, shortness of breath, pain in the chest or abdomen, bone pain, skin tumors, anemia, weakness, fatigue, poor appetite, and/or weight loss. The average survival time is approximately 9 to 12 months after diagnosis.

Routine clinical investigations to demonstrate the organ of origin are generally unproductive, with an approximate 30% rate of identification, which has not been associated with significant improvement in survival. However, for a small subset of patients with cancer of unknown primary (possibly <1%), tumor marker measurements can contribute to diagnosis of an unsuspected but potentially treatable malignancy that has presented in an atypical manner. These include gestational choriocarcinoma, GCT of the testis or ovary, prostate cancer, ovarian cancer, and breast cancer.

Tumor Markers Used in the Management of Cancers of Unknown Primary

Measurement of AFP and hCG is recommended in patients with midline metastatic disease (mediastinal nodes or presence

POINTS TO REMEMBER

- Carefully used, tumor markers can contribute usefully to patient management but awareness of their limitations is essential.
- Measurement of tissue markers including *ALK*, *BRAF*, *HER2*, *KRAS*, and the ER and PR informs selection of endocrine and immunotherapy in individual patients in NSCLC, melanoma, and/or breast cancer.
- In the management of GCT, AFP, and hCG measurement in serum is mandatory.
- Measurement of CEA in serum is recommended for post-operative follow-up of stage II and III colorectal cancer patients if further treatment is an option.
- PSA measurement in serum contributes to diagnosis of prostate cancer and may be used for detecting recurrence and monitoring therapy.
- Measurement of serum AFP, CA 125, or CA 19-9 may aid early detection of HCC, ovarian cancer, or pancreatic cancer, respectively, in appropriately selected high-risk patients.
- Opportunistic screening with panels of tumor markers is not helpful.
- Serial results are nearly always more useful than single isolated results because the main application of tumor markers is in monitoring.
- Excellent communication between clinical and laboratory colleagues is essential for optimal use of tumor markers.

of a retroperitoneal mass) to assess the possibility of a GCT. CA 125 measurement is recommended in women with symptoms that could be consistent with an occult non-germ cell ovarian malignancy, together with a gynecologic-oncologic

consultation, if indicated. Men presenting with bone metastases or multiple sites of involvement should have PSA levels assessed. Chromogranin A measurement is recommended by the European Society for Medical Oncology (ESMO) in patients with features of neuroendocrine tumors. Measurement of estrogen and PR may identify hormone-sensitive tumors amenable to specific therapy. In patients in whom a pancreatic tissue origin is suspected, measurement of CA 19-9 is recommended by the NCCN. The usual caveats apply to the use of these tumor markers in diagnosis. If their measurement identifies a likely primary source of malignancy (e.g., a GCT), monitoring protocols, if required, should be according to protocols previously described for these cancers and tumor markers.

CONCLUSION

Tumor marker measurements contribute significantly to the management of cancer patients, but considerable care is required to ensure that their use is appropriate. The clinical laboratory should proactively encourage correct test selection, sample handling, analysis, reporting, and interpretation of tumor marker results, taking particular care to remind users of the caveats associated with these tests. This is essential not only for the well-established tumor markers but also for the new generation of molecular and genetic tumor markers on which clinicians increasingly will rely on to provide optimal care. Involvement of laboratorians in developing clinical pathways that will enable optimal use of tumor markers—both the well established and the newly developing—in routine practice provides new and exciting challenges that clinical laboratories are well positioned to meet.

REVIEW QUESTIONS

- Which of the following best describes appropriate use for most serum tumor marker measurements?
 - Diagnosing or excluding a diagnosis of malignancy
 - Providing definitive information about likely prognosis in individual patients
 - Monitoring treatment effectiveness and the course of disease
 - Identifying the primary cancer by testing panels of serum tumor markers
 - Testing that is essential in the follow-up of all cancer patients
- For which of the following has measurement of a serum tumor marker been unequivocally demonstrated to be essential for early detection of disease in the appropriate screening population?
 - Breast cancer
 - Prostate cancer
 - Ovarian cancer
 - Malignant melanoma
 - Gestational trophoblastic disease
- Which of the following are mandatory for the clinical management of the majority of breast cancer patients?
 - ERs
 - CA 15-3
 - CEA
 - uPA
 - Gene profiling
- Age-related reference intervals for most tumor markers are either not relevant and/or are not universally applied for most clinical applications, but are mandatory for which of the following age groups?
 - AFP in men older than 30 years
 - AFP in neonates and infants younger than 12 months
 - hCG in men older than 30 years
 - hCG in neonates and infants younger than 12 months
 - CEA in men older than 30 years
- In women with suspected ovarian cancer the RMI is used primarily for which of the following?
 - To exclude the need for pelvic ultrasound
 - To identify whether a colorectal surgeon should be present at the time of operation

- c. To identify women with stage I disease where clear cell and endometrioid histologies predominate
- d. To assist in triaging women with ovarian cysts
- e. To determine menopausal status
- 6. Which of the following statements best describes the contribution of IS and reference reagents to tumor marker measurements?
 - a. They ensure that results are reported worldwide in the same units of measurement
 - b. They can be used as kit standards by manufacturers
 - c. Their introduction guarantees improved between-method agreement
 - d. They enable accurate calibration of all the most widely used serum tumor markers
 - e. They provide a benchmark against which the accuracy of calibration can be assessed

Kidney Function Tests

*Edmund J. Lamb, Graham R.D. Jones**

OBJECTIVES

1. Define the following:
 - Creatinine
 - Urea
 - Uric acid
 - Gout
2. Diagram the pathway that results in the formation of creatinine.
3. State the clinical usefulness of measuring serum and urine creatinine.
4. State the principle of the Jaffe reaction and list five interferences that affect this method.
5. List and describe three enzymatic assays used to measure creatinine in serum.
6. Describe “compensated assays” in relation to the measurement of creatinine.
7. Diagram the catabolic pathway that results in the formation of urea.
8. State the clinical usefulness of measuring serum urea; list the causes of increased and decreased serum urea.
9. Describe the urease approach for measuring urea in serum; list one interference that affects this method.
10. Convert serum urea nitrogen given in milligrams per deciliter to urea nitrogen in millimoles per liter.
11. Diagram the pathway that results in the formation of uric acid.
12. State the clinical usefulness of measuring serum uric acid.
13. List the causes of hyperuricemia; explain the pathogenesis of gout and urinary tract uric acid stones.
14. Compare and contrast primary and secondary gout.
15. List the causes of hypouricemia.
16. Describe the uricase method of measuring uric acid in serum; list two interferences that affect this method.
17. List and describe the proteins found in urine, including their characteristics, how they are affected in disease, and the laboratory methods of protein measurement.

KEYWORDS AND DEFINITIONS

BUN (blood urea nitrogen) Obsolete term used to report results of a urea assay, particularly in the United States.

Creatinine A nonprotein nitrogen compound derived from the spontaneous hydrolysis of creatine or the cyclization of phosphocreatine; creatinine production is relatively constant, is related to muscle mass, and is used as a marker of the glomerular filtration rate of the kidneys.

Gout A group of disorders of purine metabolism; can be due to primary (inherited) or secondary causes such as chronic kidney disease.

Hyperuricemia An excess of uric acid or urates in the blood with many causes; it is a prerequisite for the development of gout and may lead to renal disease.

Hypouricemia Decreased uric acid concentration in the blood, secondary to a number of underlying conditions such as severe hepatocellular disease and defective renal tubular reabsorption.

Jaffe reaction The reaction of creatinine with alkaline picrate to form a colored compound; this creatinine assay is subject to numerous interferences.

Urea The major nitrogen-containing metabolic product of protein catabolism in humans.

Urease methods Enzymatic assays that initially involve the hydrolysis of urea by urease to generate ammonia, which is quantified by a variety of methods.

Uric acid A nitrogenous compound derived from the catabolism of purine nucleosides.

*Data on current creatinine method usage in the United Kingdom were provided by Finlay Mackenzie from the United Kingdom National External Quality Assessment Scheme (UKNEQAS), Birmingham, United Kingdom. Further information about the UKNEQAS estimated glomerular filtration rate (GFR) scheme may be found at <<https://birminghamquality.org.uk/>>. We are grateful to the College of American Pathologists and the Royal College of Pathologists of Australasia Quality Assurance Program for data on current creatinine method usage and performance in the United States and Australasia, respectively. We also acknowledge the input of Professor Christopher Price to previous editions of this chapter.

Uricase methods A group of enzymatic assays that initially involve oxidation of uric acid by uricase to eventually produce a chromogen that is

spectrophotometrically measured to determine uric acid concentration.

Creatinine, urea, and uric acid are nonprotein nitrogenous metabolites that are cleared from the body by the kidney following glomerular filtration. Measurements of plasma or serum concentrations of these metabolites are commonly used as indicators of kidney function and other conditions. In particular, creatinine is commonly used in equations to estimate the glomerular filtration rate (GFR). Small molecular weight proteins such as cystatin C are also increasingly being used to estimate the GFR. The measurement of total protein and/or albumin in urine can give useful information regarding the integrity of the glomerular filter and tubular function.

PROTEINURIA: TOTAL PROTEIN AND ALBUMIN

Higher molecular weight proteins are retained within the circulation by the glomerular filter, and lower molecular weight proteins are freely filtered and reabsorbed and catabolized within the tubular cells. Consequently, the appearance of notable amounts of protein in the urine suggests renal disease of either the glomerulus, the tubules or both. The association between kidney disease and proteinuria dates as far back to at least the early 19th century, when Bright first described albuminous nephritis. Proteinuria can be classified as either tubular or glomerular, depending on the pattern of proteinuria observed. A third category, overflow proteinuria, is also recognized in which filtration of excessive amounts of low-molecular-weight protein exceeds the tubular capacity for reabsorption. Examples of the latter include Bence Jones proteinuria and myoglobinuria. Proteinuria is a potent risk marker for progressive kidney disease, and reduction of protein excretion is a therapeutic target. Proteinuria may be detected and measured using reagent strip devices or laboratory measurements of either total protein or albumin.

Sample Collection for Urinary Total Protein and Albumin Measurement

It is generally recognized that a 24-hour sample is the definitive means of demonstrating and quantifying the presence of proteinuria but this is a difficult procedure to control effectively, and inaccuracies in urinary collection may contribute to errors in estimation of protein losses. Overnight, first void in the morning (early morning urine [EMU]), second void in the morning, or random sample collections have also been used. Because creatinine excretion in the urine is fairly constant throughout the 24-hour period, measurement of the albumin-to-creatinine ratio (ACR) or protein-to-creatinine ratio (PCR) allows the use of a spot sample, with correction for variations in urinary concentration in an individual. Spot samples for ACR or PCR measurement generally have good diagnostic performance and correlation with the 24-hour collection, and are widely recommended for

routine clinical use. An EMU sample is often preferred because it is unaffected by orthostatic (postural) proteinuria.

The diagnosis of albuminuria requires the demonstration of increased albumin loss (either increased ACR or increased albumin in a timed collection) in at least two out of three urine samples collected in the absence of infection or an acute medical illness (Fig. 21.1). Establishing the diagnosis of albuminuria or proteinuria has both prognostic and management implications. In the setting of diabetes, the best possible metabolic control should be achieved before patients are examined for albuminuria, and patients should not be screened during other transitory illnesses. Screening should commence 5 years after diagnosis in patients with type 1 diabetes mellitus and at diagnosis in patients with type 2 diabetes, and should continue on an annual basis up to the age of 75 years. Patients demonstrating an ACR of 3.0 mg/mmol or greater should have urine samples sent to the laboratory on two other occasions (ideally within 2 months) for albumin estimation. Patients demonstrating increased ACRs in one or both of these additional samples are said to have persistent albuminuria. Diabetic nephropathy is uncommon in patients who have had type 1 diabetes for less than 5 years, and other causes of kidney disease should be considered.

Samples for urinary albumin (or total protein) measurement may be analyzed fresh, stored at 4°C for up to 1 week, or stored at -70°C for longer periods. Freezing at -20°C appears to result in loss of measurable albumin and is not recommended. For analysis, stored samples should be allowed to reach room temperature and be thoroughly mixed prior to testing.

Analytical Methods and Traceability: Urinary Total Protein

Numerous methods can be used for the measurement of protein in urine, including the original Lowry method, turbidimetry after mixing with trichloroacetic or sulfosalicylic acid, turbidimetry with benzethonium chloride (benzyl dimethyl {2-[2-(*p*-1,1,3,3-tetramethyl butylphenoxy)ethoxy] ethyl} ammonium chloride), and dye binding with Coomassie Brilliant Blue, pyrogallol red molybdate, and pyrocatechol violet-molybdate, which is used in dry-slide applications.

Total protein measurement is more difficult in urine than in serum. The concentration of urinary protein is normally low (100 to 200 mg/L) and large sample-to-sample variation in the amount and composition of proteins is common. The concentration of nonprotein potentially interfering substances is high relative to the protein concentration and is highly variable, and the inorganic ion content is high. All these factors affect the precision and accuracy of the various methods.

Because of the need for automation, the benzethonium chloride and dye-binding methods have become the most popular in current clinical use but they do not provide equal analytical specificity and sensitivity for all proteins. Concerns about different

Fig. 21.1 Suggested protocol for the further investigation of an individual demonstrating a positive reagent strip test for albuminuria/proteinuria or quantitative albuminuria/proteinuria test. Reagent strip device results should be confirmed using laboratory testing of the albumin-to-creatinine ratio (ACR) on at least two further occasions. Patients with two or more positive (≥ 3 mg albumin/mmol creatinine) tests on early morning samples 1 to 2 weeks apart should be diagnosed as having persistent albuminuria. (The possibility of postural proteinuria should be excluded by the examination of an early morning urine.) Protein-to-creatinine ratio (PCR) measurement can be substituted for the ACR but is insensitive in the detection of mild to moderately increased albuminuria/proteinuria: Approximate PCR equivalent to an ACR of 30 mg/mmol is 50 mg/mmol. ^aConsider other causes of increased ACR (e.g., menstrual contamination, uncontrolled hypertension, symptomatic urinary tract infection, heart failure, other transitory illnesses, and strenuous exercise), especially in the case of type 1 diabetes present for less than 5 years. The presence of hematuria may indicate nondiabetic renal disease. *Note:* US guidelines express albuminuria or proteinuria as mg/g creatinine, whereas other guidelines use mg/mmol creatinine. An approximate conversion factor of 0.1136 can be used to convert results in mg/g to mg/mmol. However, for clarity and pragmatism, recent guidelines have accepted decision points that are approximately equivalent: hence, when using this protocol in the United States, 300 mg/g should be substituted for 30 mg/mmol and 30 mg/g for 3 mg/mmol. C&S, Culture and sensitivity; CKD, chronic kidney disease; EMU, early morning urine; MSU, midstream urine.

responses to different proteins have led to many variants of the published methods. Most methods tend to react more strongly with albumin than with globulin and other nonalbumin proteins. As different methods are responding to different properties of proteins and the abundance of these properties varies between the proteins found in urine, the “quantity intended to be measured” is not the same for different assays. For those reasons, there is no reference measurement procedure or standardized

reference material for urinary total protein. The variety of methods in use means that significant between-laboratory variation is inevitable. This variation tends to diminish at higher concentrations of urinary total protein, presumably in part as albumin becomes the predominant protein and thus reduces a component of the between-sample variation. These methodological problems are a major reason why urine albumin is a preferred analyte for the assessment of proteinuria.

TABLE 21.1 Characteristics of Some Clinically Important Urinary Proteins

Protein	Mr (kDa)	Free Plasma Concentration (g/L)	Diameter (nm)	pI	Glomerular Sieving Coefficient	Filtered Load >(mg/L) ^a	Urinary Concentration (mg/L) ^b	% Reabsorbed

Analytical Methods and Traceability: Urinary Albumin

Urinary albumin has been measured using immunoassay since the 1960s when the first such assays became available. Urinary albumin is predominantly measured using quantitative immunoturbidimetric or immunonephelometric approaches capable of detecting albumin at low concentrations. No Joint Committee for Traceability in Laboratory Medicine (JCTLM) listed reference measurement procedure or higher order reference material is currently available for urinary albumin. To date, most urinary albumin assays have been standardized against a serum-based calibrant (ERM-DA-470k/IFCC) distributed by the Institute for Reference Materials and Measurements of the European Commission.

Reference Intervals, Definitions of Proteinuria and Albuminuria

There is no consistent definition of *proteinuria*. The upper limit of the reference interval[†] for urinary total protein loss varies between 150 and 300 mg/day, depending on the laboratory. Given average daily creatinine excretion of about 10 mmol (0.11 g), an upper limit of normal protein loss of 150 mg/day is equivalent to a urinary PCR of approximately 15 mg/mmol (130 mg/g). The protein in the urine of healthy individuals is made up of albumin (<30 mg/day) and some smaller proteins, together with proteins secreted by the tubules, of which Tamm-Horsfall glycoprotein (THG) predominates. Typical concentrations of proteins found in urine are listed in Table 21.1. Readers should note that the units of expression used for ACR and PCR differ depending on geographical location, typically whether it is inside or outside the United States.[‡]

Proteinuria is often detected at the point of care (POC) using urine reagent strip devices, and clinical proteinuria has sometimes been defined as equivalent to a color change of

“+” or greater on the relevant pad on the strip. This equates to approximately 300 mg/L of total protein or a PCR of 50 mg/mmol, or protein loss of approximately 500 mg/day (assuming an average urine volume of 1.5 L/day). Indeed, the limits for proteinuria and albuminuria are best described as clinical decision points because they are generally described or defined by expert groups rather than as the product of formal reference interval studies.

In health, relatively small amounts of albumin (<30 mg/day) are lost in the urine. In the international classification of kidney disease (see Chapter 35), proteinuria is categorized based on levels of albumin loss: A1 normal to mildly increased, less than 3.0 mg/mmol (approximately equivalent to <30 mg/g); A2 moderately increased, 3 to 30 mg/mmol (approximately equivalent to 30 to 300 mg/g); and A3 severely increased, greater than 30 mg/mmol (approximately equivalent to ≥ 300 mg/g). These categories are approximately equivalent to what would have formerly been considered normoalbuminuria, microalbuminuria, and macroalbuminuria (sometimes referred to as “clinical” or “significant” proteinuria), respectively. *Microalbuminuria* is a term that has been widely used to describe an increase in urinary albumin loss above the reference interval for healthy nondiabetic subjects, but at a level that is not generally detectable by less sensitive clinical tests such as reagent strips designed to measure total protein. The term *microalbuminuria* is somewhat misleading in that the albumin being measured is identical in form to that circulating in plasma, and the so-called microalbuminuric range refers to increased, not “micro-,” albumin losses. Current guidelines do not support the continuing use of this term, and the term *albuminuria* is used in this chapter.

Clinical Significance

The physiology and pathophysiology of renal protein handling and the clinical significance of proteinuria in specific clinical situations are discussed in more detail in Chapter 35; more general considerations follow. While reagent strip tests are commonly used in clinical practice, false negative and positive results are common. Most authors agree that positive tests require confirmation by laboratory measurement of the PCR or ACR on an early morning or random urine sample (see Fig. 21.1).

[†]Laboratories should verify that these ranges are appropriate for use in their own settings.

[‡]US guidelines express albuminuria or proteinuria as mg/g creatinine, whereas other guidelines use mg/mmol creatinine. A conversion factor of 0.1136 can be used to convert ACR or PCR results in mg/g to mg/mmol (e.g., 200 mg/g = 23 mg/mmol, 30 mg/g = 3.4 mg/mmol).

Most commonly, proteinuria reflects albuminuria and it is suggested that urinary total protein measurement can be replaced by urine albumin measurement. Strong evidence has linked increased urinary albumin loss to mortality and morbidity, including kidney disease progression, in people both with and without diabetes: albuminuria is generally held to be a more sensitive indicator of kidney disease than increased total protein loss. However, increases in albumin loss may also reflect overall changes in vascular permeability, and therefore may not indicate explicit deterioration in renal function. Increased urinary albumin loss is common among the general population and is not solely attributable to the presence of diabetes.

POINTS TO REMEMBER

Urinary Albumin

- Albumin (Mr 66 kDa) is predominantly retained in the circulation by the glomerular basement membrane due to its size and negative charge.
- In health, only small amounts of albumin are filtered. This is largely reabsorbed in the proximal tubule.
- Albuminuria may arise due to both glomerular (increased filtration) and tubular (decreased resorption) disease.
- Albumin is the predominant urinary protein in the setting of proteinuria.
- Due to high biological variability and nonrenal influences, albuminuria should be confirmed on at least two occasions, preferably with first morning samples.
- Measurement of the ACR allows the use of a spot sample with correction for variations in urinary concentration in an individual.

CREATININE

Biochemistry and Physiology

Creatine, the immediate precursor of creatinine, is synthesized in the kidneys, liver, and pancreas and is then transported in blood to other organs, such as muscle and brain, where it is phosphorylated to phosphocreatine, a high-energy compound.

Interconversion of phosphocreatine and creatine is a particular feature of the metabolic processes of muscle contraction. A proportion of free creatine in muscle (thought to be

between 1% and 2%/day) spontaneously and irreversibly converts to its anhydride waste product, creatinine. Thus the amount of creatinine produced each day in an individual is fairly constant and is related to the muscle mass. In health, the blood concentration of creatinine is also fairly constant although it may be influenced by diet (see later). Creatinine (Mr approximately 113 Da) is present in all body fluids and secretions and is freely filtered by the glomerulus. Although it is not reabsorbed to any great extent by the renal tubules, a small but notable tubular secretion is present, as well as concentration-related losses in the gut.

Sample Collection

Creatinine in serum, plasma, or urine is stable for at least 7 days at 4°C, and serum creatinine is stable during long-term frozen storage (at −20°C and below) and after repeated thawing and refreezing. However, it should be noted that delayed separation (beyond 14 hours) of serum from erythrocytes leads to a significant increase in apparent serum creatinine concentration using some kinetic Jaffe (but not enzymatic) assays, possibly as the result of release of noncreatinine chromogens from the red cells (see later). Creatinine concentration increases in blood after meals containing cooked meat, due to the conversion of creatine to creatinine, and ideally blood for serum creatinine measurement should be obtained in the fasting state.

Analytical Methods

Serum creatinine is measured in virtually all clinical laboratories as a test of kidney function. Most laboratories use adaptations of the same assay for measurements in both serum and urine. Both chemical and enzymatic methods are used to measure creatinine in body fluids.

Most chemical methods for measuring creatinine are based on its reaction with alkaline picrate. As first described by Jaffe in 1886, creatinine reacts with picrate ion in an alkaline medium to yield an orange-red complex.

A serious analytical problem with the **Jaffe reaction** is its lack of specificity for creatinine. For example, many compounds have been reported to produce a Jaffe-like chromogen, including (1) ascorbic acid, (2) blood-substitute products, (3) cephalosporins, (4) glucose, (5) guanidine, (6) ketone bodies, (7) protein, and (8) pyruvate. The degree of interference from these compounds is dependent on the specific reaction conditions chosen. The effect of ketones and ketoacids are probably of the greatest significance clinically, although the effect is very method dependent. Thus reports on acetoacetate interference vary from a negligible increase to an increase of 3.5 mg/dL (310 μmol/L) in the apparent creatinine concentration at an acetoacetate concentration of 8 mmol/L. Bilirubin is a negative interferant with the Jaffe reaction. The addition of buffering ions, such as borate and phosphate, together with surfactant, has been used to minimize the effects of this interference. In addition, ferricyanide—O'Leary method—has been added that oxidizes bilirubin to biliverdin, hence reducing its interference. For rate assays a rate-blanking approach has been successful. Noncreatinine chromogens do not generally contribute to measured urinary creatinine concentration.

The greatest success in terms of common usage and specificity has come from the use of a kinetic measurement approach in combination with the careful choice of reactant concentrations. In general, manual methods have traditionally been equilibrium methods, with 10 to 15 minutes allowed for color development at room temperature. Kinetic assays have been developed to provide more specific, faster, and automated analyses. Early studies of interferences in the kinetic methods identified two kinds of noncreatinine chromogens. In one group, the rate of adduct formation is very rapid and occurs in the first 20 s after mixing reagent and sample. Acetoacetate is an example of this type of interferant. In the second group, the rate of adduct formation does not become significant until 80 to 100 s after mixing (e.g., protein). The “window” between 20 and 80 s therefore was a period in which the rate signal being observed could be attributed predominantly to the creatinine-picric acid reaction. Thus improvement of specificity in the kinetic assays was achieved by selecting times for rate measurements 20 to 80 s after initiation of the reaction (mixing). This approach has been implemented on various automated instruments, and kinetic assays are now widely used to measure creatinine concentrations in body fluids.

Extensive literature exists on the choice of reactant concentrations and reading interval, and on the choice of wavelength and reaction temperature. Brief comments follow.

Picric Acid Concentration

The Jaffe reaction is pseudo first order with respect to picric acid up to 30 mmol/L, with the majority of methods employing a concentration between 3 and 16 mmol/L. At concentrations above 6 mmol/L, the rate of color development becomes nonlinear, so a two-point fixed interval rather than a multiple data point approach is required.

Hydroxide Concentration

The initial rate of reaction is pseudo first order with respect to hydroxide concentrations above 0.5 mmol/L. However, at 500 mmol/L there is an increased degradation of the Jaffe complex. Furthermore, at hydroxide concentrations above 200 mmol/L, the blank absorbance increases significantly.

Wavelength

Although the absorbance maximum of the Jaffe reaction is between 490 and 500 nm, improved method linearity and reduced blank values have been reported at other wavelengths, the choice varying with hydroxide concentration.

Temperature

The rate of Jaffe complex formation and the absorptivity of the complex are temperature dependent, measurable differences being observed even between 25°C and 37°C. Consequently, temperature control is an important component of assay reproducibility.

Compensation

As a result of reaction with noncreatinine chromogens, Jaffe methods often have historically overestimated true serum creatinine concentrations by up to 20% compared with high-performance liquid chromatography (HPLC) or isotope dilution mass spectrometry (IDMS) methods, at physiologic concentrations. In an attempt to adjust for this, some manufacturers have introduced so-called “compensated” Jaffe assays, in which a fixed concentration is automatically subtracted from each result. For example, Roche Diagnostics Ltd. (Lewes, Sussex, United Kingdom) has realigned its assays on the Cobas Integra and Hitachi systems by -0.20 mg/dL and -0.32 mg/dL (-18 and -28 μ mol/L), respectively. Such assays produce lower results more closely aligned with IDMS reference measurement procedures at concentrations within the reference interval. However, they make an assumption that the noncreatinine chromogen interference is a constant between samples; this is clearly an oversimplification, especially when adult and pediatric samples are compared.

Enzymatic Methods

Enzymes from a number of metabolic pathways have been investigated for the enzymatic measurement of creatinine. All of the methods involve a multistep approach leading to a photometric equilibrium (Fig. 21.2). There are primarily three approaches, described below.

Creatininase

Creatininase (EC 3.5.2.10; creatinine amidohydrolase) catalyzes the conversion of creatinine to creatine. The creatine is then detected with a series of enzyme-mediated reactions involving creatine kinase, pyruvate kinase, and lactate dehydrogenase, with monitoring of the decrease in absorbance at 340 nm (see Fig. 21.2A). Initiating the reaction with creatininase allows for the removal of endogenous creatine and pyruvate in a preincubation reaction. The kinetics of the reaction are analytically problematic and a 30-minute incubation is required to allow the reaction to reach equilibrium. This shortcoming has been overcome by a kinetic approach but with a further reduction in the method's ability to detect creatinine. Consequently, this approach is not widely used.

Creatinase and Creatinase

An alternative approach has been the use of creatinase (EC 3.5.3.3; creatine amidohydrolase) that yields sarcosine and urea, the former being measured with further enzyme-mediated steps using sarcosine oxidase (EC 1.5.3.1). This produces (1) glycine, (2) formaldehyde, and (3) hydrogen peroxide (see Fig. 21.2B) with the latter being detected and measured with a variety of methods. Care must be taken, however, because of interference (e.g., by bilirubin) in the final reaction sequence. This problem has been minimized by adding potassium ferricyanide (with limited success) or bilirubin oxidase. The potential interference caused by ascorbic acid has been overcome by the inclusion of ascorbate oxidase (L-ascorbate:oxygen oxidoreductase; EC 1.10.3.3). The influence of endogenous intermediate creatine and urea has been minimized by adding a

Fig. 21.2 (A–D) Determination of creatinine using a variety of enzymatic methods. For additional details, see text. *ADP*, Adenosine diphosphate; *ATP*, adenosine triphosphate; *NAD*, nicotinamide adenine dinucleotide.

preincubation step and then initiating the reaction with creatininase. This system has been incorporated in a POC testing device using polarographic detection. An alternative detection system involves measurement of the reduction of nicotinamide adenine dinucleotide (NAD) by formaldehyde in the presence of formaldehyde dehydrogenase (see Fig. 21.2C).

Creatinine Deaminase

Creatinine deaminase (EC 3.5.4.21; creatinine imino-hydrolase) catalyzes the conversion of creatinine to *N*-methylhydantoin and ammonia. Early methods concentrated on the detection of ammonia using either glutamate dehydrogenase or the Berthelot reaction. An alternative approach involves the enzyme *N*-methylhydantoin amidohydrolase (see Fig. 21.2D).

Dry Chemistry Systems

A number of multilayer dry reagent methods have been described for the measurement of creatinine using enzyme-mediated reactions. An early “two-slide” approach employed creatinine deaminase, with the ammonia diffusing through a semipermeable and optically opaque layer to react with bromophenol blue to give an increase in absorbance at 600 nm. A second multilayer film lacking the enzyme was used to quantitate endogenous ammonia, enabling blank correction. A later single-slide method used the creatininase-creatinase reaction sequence. Lidocaine metabolites have been reported to interfere with this method. The creatinine deaminase system described above has also been used and adapted for use as a POC testing device (see Fig. 21.2D). In all cases, the color produced in the film is quantified by reflectance spectrophotometry.

Other Methods

A definitive method employing IDMS was described by Welch in 1986. Gas or liquid chromatography-IDMS (GC-IDMS, LC-IDMS) are now accepted as the methods of choice for establishing the true concentration of creatinine in serum because of its excellent specificity and low imprecision. GC- and LC-IDMS methods have been approved by the JCTLM as reference measurement procedures for serum creatinine.

Quality Issues and Preanalytical Considerations With Creatinine Methods

Assessment of the methods used for the measurement of creatinine is complex by virtue of the number of variants of the Jaffe reaction and the innovations attempted using enzymatic procedures to overcome the limitations of the former. Although enzymatic methods are more expensive, they are used in dry chemistry systems (with their lower reagent requirement), including some POC testing devices. Kinetic Jaffe approaches generally predominate in wet chemistry analytical systems. Any laboratorian assessing a new creatinine method (e.g., as part of an analyzer purchase) should review the data for that method on common interferences. Despite criticism of the Jaffe methods, good correlation has been noted invariably between them and enzymatic procedures, with differences likely to be due as much to calibration as to interference.

Different methods for assaying serum creatinine have varying degrees of accuracy and imprecision. Mean within-individual biological variation for serum creatinine has been reported as approximately 6.0%, indicating a desirable analytical performance goal of less than 3.0%. Intralaboratory imprecision at a concentration of 88 $\mu\text{mol/L}$ varies between approximately 2.0 and 8.4%. Clearly, many laboratories are therefore outside desirable and even minimum performance standards. Proficiency studies demonstrate that while between-laboratory CVs of approximately 3% are achievable within method groups, overall between-laboratory agreement across methods is much poorer. Further, within- and between-laboratory agreement deteriorates as serum creatinine concentration falls to within and below the reference interval; the exponential relationship between serum creatinine and GFR means that imprecision at lower creatinine concentrations contributes to greater error in GFR estimation than at higher creatinine concentrations.

Over the past 20 years, appreciation of chronic kidney disease (CKD) as a major public health issue and of its identification, staging and monitoring using GFR-estimating equations has led to increased focus on the measurement of creatinine. Creatinine-based estimates of GFR (see later) will clearly vary, depending on how accurate the creatinine measurement used in the calculation is. The more a method overestimates “true” creatinine, the greater will be the underestimation of GFR, and vice versa (see later).

Traceability of Serum Creatinine Measurement

Standardized serum matrix reference materials (SRM967) with known creatinine concentrations (0.80 mg/dL [71 $\mu\text{mol/L}$]

and 4.00 mg/dL [354 $\mu\text{mol/L}$]) have been prepared by the National Institute of Standards of Technology (NIST) and included in a list of higher order reference materials by the JCTLM. The material was value-assigned using mass spectrometry and issued in 2007. This material, in combination with GC-IDMS reference methodology, was used by reagent manufacturers to restandardize their methods and since 2009 most clinical laboratory methods have had calibration traceable to the reference measurement procedure and standard.

Although undoubtedly desirable, it must be recognized that standardization is only one arm of the problem. Standardization will not solve the problems of noncommutable calibrator materials and differential reactivity with noncreatinine chromogens across different patient samples, which can be resolved only by the use of highly specific creatinine methods. Wider adoption of enzymatic methods could further improve between-laboratory agreement in creatinine measurement, but these methods are used by a minority of laboratories at present.

Reference Intervals

Reference intervals for serum creatinine are method dependent. A systematic review of creatinine reference intervals in which studies were included only when, in particular, their calibration was traceable to the reference IDMS procedure; proposed adult reference intervals of 0.72 to 1.18 mg/dL (64 to 104 $\mu\text{mol/L}$) in men and 0.55 to 1.02 mg/dL (49 to 90 $\mu\text{mol/L}$) in women. These data were derived using an enzymatic (Roche Diagnostics Ltd) assay. Serum creatinine concentration in patients with untreated end-stage renal disease (ESRD) may exceed 11 mg/dL (1000 $\mu\text{mol/L}$).

Urinary creatinine excretion is higher in men (14 to 26 mg/kg per day, 124 to 230 $\mu\text{mol/kg}$ per day) than in women (11 to 20 mg/kg per day, 97 to 177 $\mu\text{mol/kg}$ per day). Creatinine excretion decreases with age. Typically, for a 70 kg man, creatinine excretion will decline from approximately 1640 to 1030 mg/day (14.5 to 9.1 mmol/day) with advancing age from 30 to 80 years. The measurement of urinary creatinine excretion has been found to be a useful indication of the completeness of a timed urine collection. Creatinine excretion is often used as a method of normalizing the urinary excretion of analytes, that is, the excretion of the test analyte (in millimoles or grams) is divided by the total amount of creatinine (in millimoles or grams) excreted in the same urine specimen. This method is a rough correction for volume differences between patient specimens. Similarly, expressing the concentration of a substance as a ratio to the creatinine concentration is a useful method of adjusting for urinary concentration differences in random (“spot”) urine samples.

Clinical Significance

Serum creatinine concentration is maintained within narrow limits predominantly by glomerular filtration. Consequently, both serum creatinine concentration and its renal clearance (“creatinine clearance”) have been used as markers of the GFR. The application and limitations of these tests are discussed later in this chapter.

POINTS TO REMEMBER**Creatinine**

- Creatinine is produced at a fairly constant rate within an individual as a result of a breakdown of creatine within muscle tissue.
- Creatinine is freely filtered at the glomerulus and also secreted in the tubules to a lesser extent.
- Because it is predominantly excreted by the kidneys, plasma creatinine concentration is inversely proportional to GFR (halving the GFR approximately doubles the serum creatinine).
- In addition to GFR, other factors related to creatinine production affect plasma creatinine concentration, including age, gender, race, muscularity, certain drugs, diet, and nutritional status.
- Estimated GFR (eGFR) using the CKD-EPI_{creat} equation is currently recommended for clinical use (see Table 21.2).

CYSTATIN C**Biochemistry and Physiology**

Cystatin C is a low-molecular-weight (12.8 kDa) protein synthesized by all nucleated cells whose physiologic role is that of a cysteine protease inhibitor. The gene has been sequenced, and the promoter region has been identified as that of the housekeeping type, with no known regulatory elements, and, consequently, the rate of cystatin C release into the circulation was initially considered to be constant. Over time a number of factors have been identified that can affect cystatin C production and thus the circulating concentration (e.g., thyroid hormone concentration). Unlike creatinine, muscle mass does not have a major effect on cystatin C concentration.

Cystatin C is removed from the circulation by the kidneys with no known extrarenal routes of elimination. Due to its small size and high isoelectric point (pI 9.2), it is more freely filtered than some other putative protein markers of GFR. Following filtration, cystatin C is essentially fully resorbed and broken down in the tubules usually leading to very low concentrations in the urine.

In addition to renal function and pathophysiological factors, serum cystatin C concentrations are also affected by age, gender, pregnancy, weight, and height. The influences of age and gender are taken into account with some cystatin C-based GFR estimating equations (see later).

Analytical Methods

Cystatin C is measured by immunoassay, the most practical approaches being particle-enhanced turbidimetric or nephelometric immunoassay, which can run on automated chemistry analyzers or specific nephelometers. Using these assays, a between-day imprecision of CV 3% to 6% can be expected at the upper limit of the reference interval (≈ 1.00 mg/L) and less than 3% at higher values. The use of immunoassays makes cystatin C relatively free of the interferences that affect Jaffe creatinine assays although the reagents are markedly more expensive than those used for creatinine measurement.

Traceability of Cystatin C Measurement

An international standard, ERM-DA471/IFCC Cystatin C in human serum, has been developed by an International Federation of Clinical Chemistry and Laboratory Medicine (IFCC) working party. The material has verified commutability and is listed on the JCTLM database. Most manufacturers have restandardized their assays against this material, and the use of these traceable assays in research and in the routine laboratory is recommended to allow direct comparability of results.

Reference Intervals

While single reference intervals for adult males and females of all ages are commonly used, typically of the order 0.6 to 1.1 mg/L, it is known that cystatin C concentrations are higher in males than females and climb throughout adult life, reflecting the fall in GFR with advancing age seen in most populations. In a similar manner to serum creatinine, clinical decisions based on cystatin C are more likely to be made using eGFR values derived from cystatin C than on the serum cystatin C concentration itself, making the reference interval less relevant as a decision support tool.

Clinical Significance

Because cystatin C is produced at a relatively constant rate, freely filtered at the glomerulus and neither secreted nor reabsorbed intact in the proximal tubule, its concentration in serum can serve as a marker of GFR, with GFR being related to the reciprocal of serum cystatin C. In a similar manner to serum creatinine, equations have been developed to estimate GFR based on serum cystatin C with or without added demographic variables and with or without serum creatinine; some of these equations are given in Table 21.2. The Chronic Kidney Disease-Epidemiology Collaboration (CKD-EPI) cystatin C equations are well validated in adults.

Generally the use of cystatin C equations provides some, albeit modest, improvement over equations based on serum creatinine alone. An increasing body of evidence suggests that the use of cystatin C GFR-estimating equations gives improved risk prediction of death and kidney failure unrelated to the accuracy of the GFR estimation; this improved predictive ability may relate to non-GFR determinants of serum cystatin C concentration. To delineate risk, KDIGO suggest that, if confirmation of CKD is required, cystatin C should be measured in adults who have creatinine-eGFR between 45 and 59 mL/min per 1.73 m² and who do not have markers of kidney damage.

POINTS TO REMEMBER**Cystatin C**

- Cystatin C is a low-molecular-weight protein (12.8 kDa) produced at a fairly constant rate from most body cells.
- A modest increase in production is seen in obesity, hyperthyroidism, and inflammation.
- Cystatin C is removed from the circulation by the kidneys. It is freely filtered at the glomerulus and largely destroyed in the tubules.
- The clinical utility of cystatin C can be improved with a GFR estimating equation—for example, the CKD-EPI_{cystatin C} equation.

TABLE 21.2 Representative Glomerular Filtration Rate Estimating Equations for Use in Adults

Abbreviation	Glomerular Filtration Rate Equation
Cockcroft and Gault	$[(140 - \text{age}) \times \text{weight}] \times 1.23 / (\text{Scr}) \times 0.85$ (if female)
MDRD (ID-MS traceable)	$\text{GFR (mL/min per } 1.73 \text{ m}^2) = 175 \times (\text{Scr} \times 0.01131)^{-1.154} \times (\text{age})^{-0.203} \times (1.210 \text{ if patient is black}) \times (0.742 \text{ if patient is female})$
CKD-EPI _{creat}	$141 \times \min(\text{Scr} \times 0.01131/\kappa, 1)^\alpha \times \max(\text{Scr} \times 0.01131/\kappa, 1)^{-1.209} \times 0.993^{\text{age}} \times 1.018$ (if female) $\times 1.159$ (if black), where Scr is serum creatinine, κ is 0.7 for females and 0.9 for males, α is -0.329 for females and -0.411 for males, min indicates the minimum of Scr/ κ or 1, and max indicates the maximum of Scr/ κ or 1.
CKD-EPI _{cys}	$133 \times \min(\text{Scys}/0.8, 1)^{-0.499} \times \max(\text{Scys}/0.8, 1)^{-1.328} \times 0.996^{\text{Age}} \times 0.932$ (if female), where min indicates the minimum of Scys/ κ or 1, and max indicates the maximum of Scys/ κ or 1.
CKD-EPI _{creat-cys}	$135 \times \min(\text{Scr} \times 0.01131/\kappa, 1)^\alpha \times \max(\text{Scr} \times 0.01131/\kappa, 1)^{-0.601} \times \min(\text{Scys}/0.8, 1)^{-0.375} \times \max(\text{Scys}/0.8, 1)^{-0.711} \times 0.995^{\text{Age}} \times 0.969$ (if female) $\times 1.08$ (if black), where Scr is serum creatinine, Scys is serum cystatin C, κ is 0.7 for females and 0.9 for males, α is -0.248 for females and -0.207 for males, min indicates the minimum of Scr/ κ or 1, and max indicates the maximum of Scr/ κ or 1.
BIS1	$3736 \times (\text{Scr} \times 88.4)^{-0.87} \times \text{age}^{-0.95} \times 0.82$ (if female)
BIS2	$767 \times \text{Scys}^{-0.61} \times \text{Scr}^{-0.40} \times \text{age}^{-0.57} \times 0.87$ (if female)
CAPA cystatin C equation	$130 \times \text{cystatin C}^{-1.069} \times \text{age}^{-0.117} - 7$

Age is given in years, serum creatinine in micromoles per liter, serum cystatin C (Scys) in milligram per liter, and weight in kilograms.

UREA

Biochemistry and Physiology

Urea ($\text{CO}[\text{NH}_2]_2$, Mr 60 Da) is the major nitrogen-containing metabolic product of protein catabolism in humans. During the process of protein catabolism, nitrogen derived from amino acids enters the urea cycle via intermediates, which include aspartate and ammonia. Urea is synthesized exclusively in the liver by the enzymes of the urea cycle (Fig. 21.3). The rate of urea production is dependent on the rate of protein catabolism from both dietary and endogenous sources, the latter being largely from muscle. Urea is distributed evenly throughout the total body water due to its ability to diffuse through most cell membranes facilitated by urea transporter proteins, and is therefore described as having a volume of distribution equal to the total body water.

Renal excretion accounts for more than 90% of urea removal from the body, with some losses through the gastrointestinal (GI) tract and skin. Urea is freely filtered at the glomerulus and, while it is neither actively reabsorbed nor secreted by the tubules, over 50% of urea moves passively out of the renal tubule, into the renal interstitium and back into the plasma. The back-diffusion of urea is dependent on urine flow rate, with less entering the interstitium in high-flow states (e.g., pregnancy) and more with low-flow situations (e.g., prerenal reduction in GFR due to fluid losses). Because water is resorbed to a far greater extent than the urea back-diffusion, urea is markedly concentrated during the process of urine formation, being present in urine at about 20 to 100 times the plasma concentration and is therefore the major contributor to urine

Fig. 21.3 The urea cycle pathway. AAS, Argininosuccinate synthetase; AL, argininosuccinate lyase; AR, arginase; ADP, adenosine diphosphate, ATP, adenosine triphosphate; CPS I, carbamoyl phosphate synthetase I (*N-acetylglutamate as positive allosteric effector); OTC, ornithine transcarbamylase; P_i , inorganic phosphate.

osmolality. The role of urea in the functioning of the kidney is complex, involving specific urea transporters under the action of vasopressin.

Analytical Methods

The vast majority of urea measurements in clinical laboratories are undertaken using enzymatic methods based on preliminary hydrolysis of urea with urease to generate ammonium ion, which then is quantitated. This approach has been used in end-point, kinetic, conductimetric, and dry chemistry systems.

The analytical specificity of all routine methods is good and typical assay precision is usually small compared with the biological variation of serum urea indicating good analytical performance. Reference materials, both pure and matrix matched, as well as reference methods based on IDMS are available for urea and are listed on the JCTLM database, and assays from different providers generally provide acceptably consistent results.

Reference Intervals

Serum urea concentrations are higher in men than in women, and there is an increase in the upper reference limit throughout adult life by a factor of about 50% from the 20s to the 70s. Pregnancy is associated with lower urea concentrations compared with age-matched nonpregnant women due to the associated glomerular hyperfiltration. In the pediatric age range, from after the first 2 weeks, the first year of life is associated with low serum urea, followed by a rise to slightly above adult concentrations to the age of about 10 years, then falling to young adult values by the late teens.

A reference interval for serum urea in healthy adults is 2.1 to 7.1 mmol/L (6 to 20 mg/dL expressed as urea nitrogen). Specific reference intervals will depend on the age, diet, and gender balance of the reference population (e.g., in adults older than 60 years of age), a higher reference interval (e.g., 2.9 to 8.2 mmol/L [8 to 23 mg/dL]) may be used. On an average protein diet, urinary urea excretion expressed as urea nitrogen is 12 to 20 g/day (430 to 710 mmol/day).

The term **blood urea nitrogen (BUN)** is used in some countries to refer to serum urea tests, with results reported as mg/dL of BUN. The SI system recommends the use of the term urea, expressed in mmol/L. To convert mg/dL BUN to mmol/L urea multiply the value by 2.8 (or by 0.357 for the reverse).

Clinical Significance

Measurement of blood and serum urea has been used for many years as an indicator of kidney function. However, it is generally accepted that creatinine measurement provides better information in this respect. Serum and urinary urea measurement may still provide useful clinical information in particular circumstances. The measurement of urea in dialysis fluids is widely used in assessing the adequacy of renal replacement therapy (see [Chapter 35](#)).

Urea concentration in serum is significantly affected by the rate of production as well as the rate of removal, which not only limits its value as a test of kidney function, but also allows its use for a range of other factors. For example, urea production, and therefore plasma concentration, is increased by a high-protein diet, increased endogenous protein catabolism, such as occurs in many hospitalized patients, reabsorption of blood proteins after GI hemorrhage, and treatment with cortisol or its synthetic analogues.

Urea removal from the circulation can be reduced due to any cause of reduced glomerular filtration, including prerenal, renal, or postrenal factors. The differential response of urea relative to creatinine can be useful diagnostically. In obstructive postrenal conditions (e.g., malignancy, nephrolithiasis, and prostatism), both serum creatinine and urea concentrations will be increased, although in these situations the increase in serum urea is greater than that of creatinine because of increased back-diffusion. These considerations give rise to the main proposed clinical use of serum urea—namely, its measurement in conjunction with that of serum creatinine and subsequent calculation of the urea to creatinine ratio. This can be used as a crude discriminator between prerenal and intrinsic causes of reduced GFR. For a normal individual on a normal diet, the reference interval for the ratio is between about 49 and 81 mmol urea/mmol creatinine (12 and 20 mg urea/mg creatinine). In the setting of known acute kidney injury (AKI), a raised urea to creatinine ratio (>81 mmol/mmol) is thought to be more indicative of a prerenal cause than an intrinsic renal cause, such as acute tubular necrosis.

A low serum urea concentration occurs in the setting of low protein intake—for example, starvation or anorexia nervosa. This is less commonly seen among hospital inpatients who, although often do not consume adequate nutrients, do not exhibit a low serum urea due to the presence of significant catabolism of endogenous protein. Low serum urea concentration can also be seen with end-stage liver disease due to decreased urea synthesis.

Measurement of urinary urea output provides a crude index of overall nitrogen balance and may be used as a guide to replacement in patients receiving parenteral nutrition.

URIC ACID (URATE)

Biochemistry and Physiology

Uric acid ($C_5H_4N_4O_3$, Mr 168) is the major product of catabolism of the purine nucleosides, adenosine, and guanosine in humans ([Fig. 21.4](#)). These precursors are metabolized into uric acid in a series of metabolic steps finishing with the conversion of xanthine to uric acid by the action of xanthine oxidase. The bulk of excreted uric acid arises from the degradation of endogenous nucleic acids (approximately 400 mg/day) with a lesser contribution from dietary sources (300 mg/day). Overproduction of uric acid may result from increased synthesis of purine precursors. In humans, approximately 75% of

Fig. 21.4 Metabolism of purines: (A) Synthesis. (B) Catabolism. (C) Salvage pathways. *ATP*, Adenosine triphosphate.

uric acid excreted is lost in the urine; most of the remainder is secreted into the GI, where it is degraded to allantoin and other compounds by bacterial enzymes.

Renal handling of uric acid is complex and involves four sequential steps: (1) glomerular filtration of virtually all the uric acid in capillary plasma entering the glomerulus; (2) near complete reabsorption in the proximal convoluted tubule; (3) secretion into the distal portion of the proximal tubule; and (4) further reabsorption in the distal tubule. The net urinary excretion of uric acid is 6% to 12% of the amount filtered.

The physicochemical properties of uric acid are important in considering uric acid concentrations in the circulation, in tissue, and in the kidneys. The first pK_a of uric acid is 5.75; above this pH, uric acid exists chiefly as urate ion, which is more soluble than uric acid. At a urine pH below 5.75, uric acid is the preponderant form. On the basis of the ionization form in the circulation, it has been proposed that urate should be the preferred term rather than uric acid when describing serum measurements.

Sample Collection

Most blood collection tubes are suitable for sample collection and urate is sufficiently stable that no special collection or sample handling conditions are required. Traditionally, urinary uric acid excretion is determined in a 24-hour urine sample. If analysis is not undertaken promptly, alkalization of the sample is recommended to maintain uric acid in solution.

Analytical Methods

Methods based on the enzyme uricase ([urate:oxygen] oxidoreductase; EC 1.7.3.3) are the most commonly used routine methods for measuring uric acid. Uricase acts on uric acid to produce allantoin, hydrogen peroxide, and carbon dioxide. The reaction can be observed in either the kinetic or the equilibrium mode. Most current enzymatic assays for serum urate involve a peroxidase system coupled with one of a number of oxygen acceptors to produce a chromogen. The step for quantitation of the hydrogen peroxide produced is sometimes referred to as a Trinder reaction. One popular method measures hydrogen peroxide with the aid of horseradish peroxidase and an oxygen acceptor to yield a chromogen in the visible spectrum. The most common oxygen acceptor used is 4-aminophenazone, together with phenol or a substituted phenol. The JCTLM lists pure substance and matrix matched certified reference materials for uric acid as well as IDMS reference methods and reference measurement services for analysis in serum and urine. Evidence suggests that most routine methods are meeting clinical needs. Interference in Trinder assays can be caused by antioxidants such as ascorbate (e.g., intravenous vitamin C), bilirubin, and unspecified interferants in serum from patients with kidney failure. Rasburicase is a urate-consuming enzyme (urate oxidase) used to treat patients with tumor lysis syndrome. Rasburicase can lower serum urate concentrations in blood collection tubes *ex vivo* unless both whole blood and serum are cooled before and after separation or treated by acidification.

Reference Intervals

The serum urate concentration increases gradually with age, rising about 10% between the ages of 20 and 60 years. A significant rise is seen in women after menopause, reaching concentrations similar to those found in men. Additionally, higher concentrations of serum urate are found with increases in waist circumference, body mass index, and other components of the metabolic syndrome. A population reference interval may require partitioning on the basis of gender and age, and will be affected by the metabolic status of the population. It can be argued that a clinical decision point for the relevant clinical question may be more useful than a population reference interval given the interaction with common comorbidities. A reference interval for serum urate has been reported to be 3.5 to 7.2 mg/dL (0.21 to 0.43 mmol/L) for males and 2.6 to 6.0 mg/dL (0.16 to 0.36 mmol/L) for females.

During pregnancy, serum urate concentrations fall during the first trimester and until about 24 weeks' gestation, when values begin to rise and eventually exceed nonpregnant concentrations. Urinary uric acid excretion in individuals on a diet containing purines is 250 to 750 mg/day (1.5 to 4.5 mmol/day). Excretion may decrease by 20% to 25% on a purine-free diet to less than 400 mg/day (2.4 mmol/day).

Clinical Significance

The most common clinical use for urate assessment is risk assessment for gout and determination of therapy adequacy. Other clinical conditions where serum urate measurements have potential utility include cardiovascular risk assessment and a diagnosis of preeclampsia. Urine uric acid measurements may play a role in assessing the cause of hyperuricemia and in assessing the risk of renal stone formation.

Hyperuricemia

The major causes of **hyperuricemia** are summarized in [Box 21.1](#). Asymptomatic hyperuricemia is frequently detected through biochemical screening, although there is no evidence for clinical benefit resulting from this practice.

Gout

Gout occurs when monosodium urate precipitates in joints and tissues from supersaturated body fluids. These deposits of urate are responsible for the clinical signs and symptoms. Gouty arthritis is caused by urate crystal formation in joint fluid and may be associated with deposits of crystals (tophi) in tissues surrounding the joint. The deposits may occur in other soft tissues as well, and wherever they occur they elicit an intense inflammatory response. The first metatarsophalangeal joint (big toe) is the classic site for gout. Gout is a condition characterized by occasional attacks and long periods of remission. It is important to appreciate that the serum uric acid concentration is often normal during an acute attack and is not a component of the diagnostic criteria. The demonstration of uric acid crystals in joint aspirate fluid is the pathognomonic sign for gout. For details on the diagnostic criteria and associated evidence base, readers are referred to the European League Against Rheumatism (EULAR)

BOX 21.1 Causes of Hyperuricemia**Increased Formation****Primary**

Idiopathic
Inherited metabolic disorders

Secondary

Excess dietary purine intake
Increased nucleic acid turnover (e.g., leukemia, myeloma, radiotherapy, chemotherapy, trauma)
Psoriasis
Altered ATP metabolism
Tissue hypoxia
Preeclampsia
Alcohol

Decreased Excretion**Primary**

Idiopathic

Secondary

Acute or chronic kidney disease
Increased renal reabsorption
Reduced secretion
Lead poisoning
Preeclampsia
Organic acids (e.g., lactate and acetoacetate)
Salicylate (low doses)
Thiazide diuretics
Trisomy 21 (Down syndrome)

ATP, Adenosine triphosphate.

guidelines. This report also provides information on the risk factors for the development of gout, which represent those for increasing concentrations of serum uric acid; of these, the major ones are male gender, CKD, hypertension, and obesity.

Gout may be classified as primary or secondary. Primary gout is associated with essential hyperuricemia, which has a polygenic basis. In more than 99% of cases, the cause is uncertain, but the condition is probably due to a combination of metabolic overproduction of purines, decreased renal excretion, and increased dietary intake. Very rarely, primary gout is attributable to inherited defects of enzymes in the pathways of purine metabolism.

Secondary gout is a result of hyperuricemia attributable to several identifiable causes such as CKD; as a consequence of administration of drugs (in particular diuretics); and ketoacidosis or to lactic acidosis (by reducing tubular secretion of urate). Increased nucleic acid turnover and a consequent increase in catabolism of purines may be encountered in rapid proliferation of tumor cells and in massive destruction of tumor cells on therapy with certain chemotherapeutic agents.

Management of an acute attack of gout can be divided into broad strategies: management of the attack and the prevention of subsequent attacks. The main focus for acute management is pain relief. Avoidance of subsequent attacks is based on lifestyle and pharmacotherapy with the aim of reducing

plasma urate, which is monitored to assess therapeutic success. An evidence-based treatment target for prevention of gout recurrence is a serum urate concentration less than 0.36 mmol/L.

Kidney Disease

Kidney disease associated with hyperuricemia may take one or more of several forms: (1) gouty nephropathy with urate deposition in renal parenchyma, (2) acute intratubular deposition of urate crystals, and (3) urate nephrolithiasis.

Kidney Stones

Uric acid kidney stones occur in approximately one in five patients with clinical gout. Although serum and urinary uric acid should be measured in stone formers, many uric acid stone formers do not demonstrate hyperuricuria or hyperuricemia. Uric acid stone formation is promoted by the passage of a persistently acid urine with undissociated uric acid (pK_a 5.57) being relatively insoluble, whereas urate at pH 7.0 is greater than 10 times more soluble. Pure uric acid stones account for approximately 8% of all urinary tract stones and, unlike many of the calcium-containing stones, are radiolucent. Allopurinol is the mainstay of treatment of uric acid stones.

Preeclampsia

Preeclampsia is pregnancy-induced hypertension associated with proteinuria (>0.3 g/day) and often edema and may become life threatening for the mother or the fetus (see [Chapter 44](#)). The role of uric acid measurement in the management of preeclampsia is uncertain: measurement recommendations appear in some guidelines but not others. If assessing urate concentrations in this setting, it is important to use pregnancy-specific reference intervals.

Inherited Diseases

Hyperuricemia can be a feature of several inherited disorders of purine metabolism, most of which are rare, and the diagnosis requires support from a specialist purine laboratory. Readers are referred to specialist textbooks for further information.

Hypouricemia

Hypouricemia, often defined as serum urate concentrations less than 2.0 mg/dL (0.12 mmol/L), is much less common than hyperuricemia. It may be secondary to severe hepatocellular disease with reduced purine synthesis or xanthine oxidase activity, or defective renal tubular reabsorption of uric acid. Defective reabsorption may be congenital, as in generalized Fanconi syndrome, or acquired. Overtreatment of hyperuricemia with allopurinol or uricosuric drugs and cancer chemotherapy with 6-mercaptopurine or azathioprine (inhibitors of de novo purine synthesis) may also cause hypouricemia.

Cardiometabolic Outcomes and Urate

Recent publications have highlighted positive associations between serum urate concentrations and a range of important cardiovascular and health outcomes that are generally

associated with the metabolic syndrome (e.g., obesity and insulin resistance, hypertension and renal disease, cardiovascular disease, type 2 diabetes, and all cause and cardiovascular mortality). More important, as well as indicating risk for patients with hyperuricemia, these relationships occur within the usually described “normal range” with the higher urate values associated with increasing risk. While these associations appear to be robust, it is less clear whether or not there is a causal association or whether urate-lowering therapy may be beneficial. The role of measurement of urate in the routine laboratory, validated clinical decision points, and appropriate management of patients based on the results remains to be determined; however, it is likely that there will be more roles for this analyte in the future.

POINTS TO REMEMBER

Urate

- Urate (uric acid) is the major end product of catabolism of the purine nucleosides.
- Excretion of urate is predominantly renal.
- Reference intervals for urate are influenced by many factors, including age, gender, menopausal status, diet, and waist circumference.
- Gout occurs when monosodium urate precipitates in joints and tissues from supersaturated body fluids, eliciting an intense inflammatory response.
- When treating gout, a target urate concentration of <6 mg/dL (<0.36 mmol/L) is used.

ASSESSMENT OF KIDNEY FUNCTION: GLOMERULAR FILTRATION RATE

The GFR is widely accepted as the best overall measure of kidney function. Progressive decrease in GFR is associated with the clinical signs and laboratory changes of kidney damage in all forms of kidney disease. Measuring GFR in established disease is useful in targeting treatment, monitoring progression, and predicting the point at which renal replacement therapy will be required. It is also used as a dosage guide to prevent toxicity by drugs excreted by the kidneys. There are a range of methods available to measure and estimate the GFR.

The Concept of Clearance

All tests for GFR are based on the clearance of a substance from the circulation by the kidneys. Renal clearance of a substance is defined as the volume of plasma from which the substance is completely cleared (removed) by the kidneys per unit of time. Provided a substance S is freely filtered in the glomerulus and neither secreted, resorbed, nor metabolized in the tubules, the renal clearance of S is equal to the GFR, and carries the same unit dimension (volume/time). Under these conditions the following equations apply.

$$\text{GFR} \times \text{PS} = \text{US} \times \text{V} \quad (21.1)$$

$$\text{GFR} = (\text{US} \times \text{V}) / \text{PS} \quad (21.2)$$

where GFR = the flow rate in mL per minute of plasma through the glomerular membranes, equivalent to a clearance in units of mL of plasma cleared of a substance per minute; US = urinary concentration of the substance; V = volumetric flow rate of urine in milliliter per minute; and PS = plasma concentration of the substance (in the same units as the urinary concentration of the substance).

The units of milliliter per minute is the most commonly used unit for GFR and is recommended for universal adoption to avoid confusion from the use of different units.

Kidney size and GFR are roughly proportional to body size, with larger people having a higher GFR and vice versa; to remove this effect it is conventional to adjust GFR to a standard body surface area (BSA) of 1.73 m². There are a number of formulae available to enable BSA estimation (e.g., Du Bois and Du Bois, Haycock). A variety of markers, both exogenous (radioisotopic and nonradioisotopic) and endogenous, have been used to measure or estimate GFR with the choice of marker and procedure based on cost and availability as well as accuracy.

Exogenous Markers of Glomerular Filtration Rate

Protocols for direct measurement of GFR are based on exogenous markers, with urinary clearance of inulin considered to be the “gold standard.” There are many other exogenous markers and also different protocols for GFR determination. Markers may be given intravenously either by continuous infusion or single bolus and measured in serial urine or blood collections. The nonradioisotopic markers include inulin and iothexol, and the radiolabeled markers include labeled EDTA, DTPA, and iothalamate. Determination of GFR with exogenous markers is available in many hospitals and should be considered for clinical use when accurate GFR determination is required (e.g., prior to kidney donation, when dosing particularly toxic medications).

Endogenous Markers of Glomerular Filtration Rate

The most widely used endogenous marker of GFR is creatinine, expressed as its serum concentration, as renal clearance or included in equations for eGFR. Although a range of other low-molecular-weight compounds have been investigated for clinical use, only creatinine and cystatin C are recommended for routine use.

Creatinine

Serum creatinine concentration is a product of the rate of release into the circulation as well as the rate of removal, and awareness of the influence of both of these factors is required for an understanding of the use of creatinine measurements. Creatinine is produced in muscle from creatine at a fairly constant rate proportional to the amount of muscle present. Because muscle mass is affected by age, gender, race, nutrition, exercise, and other factors, the rate of production is variable between different people. The major route of creatinine removal from the circulation is by free filtration at the renal glomerulus although there is some additional loss into

Fig. 21.5 The relationship between serum creatinine concentration and glomerular filtration rate (GFR), measured as the clearance of inulin, in 171 patients with glomerular disease. The hypothetical relationship between GFR and serum creatinine is shown as a *continuous line*, assuming that only filtration of creatinine takes place. The *dashed horizontal line* represents an upper limit of normal for serum creatinine (1.4 mg/dL, 124 μ mol/L), which is widely used at the time of publication. Because of creatinine secretion and/or a creatinine deficit through gut excretion, the serum creatinine consistently overestimates the GFR. (From Shemesh, O., Golbetz, H., Kriss, J. P., & Myers, B.D. [1985]. Limitations of creatinine as a filtration marker in glomerulopathic patients. *Kidney International*, 28, 830–838.)

the urine by tubular secretion and by loss through the GI tract. Due to the key role of glomerular filtration in creatinine removal, the concentration of creatinine in the circulation is inversely related to GFR—that is, for the same creatinine production, a halving of the GFR will lead to an approximate doubling of the serum creatinine concentration. Importantly, creatinine is convenient and cheap to measure and is widely available.

A range of factors affect creatinine metabolism and measurement, which are important when they are used to assess renal function. Drug effects can be due to blockage or tubular secretion (e.g., cimetidine, trimethoprim) or interference in creatinine assays. In patients with CKD, extrarenal clearance of creatinine becomes important when caused by degradation as a result of bacterial overgrowth in the small intestine, further blunting the anticipated increase in plasma creatinine in response to falling GFR. An important factor for any creatinine-based interpretation is that serum creatinine can remain within the reference interval until notable kidney function has been lost. Additionally, serum creatinine measurement will not detect people with mildly reduced GFR (60 to 89 mL/min per 1.73 m²) and will fail to identify many patients with CKD and category 3A GFR (45 to 59 mL/min per 1.73 m²) (Fig. 21.5). Thus, although an increased serum

creatinine concentration generally equates with impaired kidney function, a normal serum creatinine does not necessarily equate with normal kidney function. However, while the interpretation of creatinine concentration against population-based decision points is insensitive for the detection of CKD, changes in serum creatinine within an individual may be used as a sensitive tool for detecting changes in kidney function, whether the results are within or outside population reference intervals. In this setting, changes greater than expected by chance (i.e., that due to biological and analytical variation) are likely to indicate a significant change in GFR in a patient.

Creatinine Clearance

A measured creatinine clearance, performed using a 24-hour urine collection and serum collection, ideally during this period, has been used for many years as a marker of GFR. However, the difficulty in obtaining a complete, timed 24-hour urine collection, together with a high within-subject biological variation in creatinine excretion and the known overestimation of GFR due to creatinine tubular secretion make this test both inaccurate and imprecise as a measure of GFR. In spite of these limitations, creatinine clearance remains in common use in recommendations for drug-dosing decisions (see later).

Estimating Glomerular Filtration Rate

The approximate mathematical relationship between serum creatinine and GFR ($GFR \propto 1/\text{serum creatinine}$) can be improved by correcting for some of the confounding variables that influence this relationship. Many different equations have been derived that estimate GFR using serum creatinine and inputs of some or all of gender, body size, race, and age. These generally produce a better estimate of GFR than serum creatinine alone or measured creatinine clearance, and professional societies throughout the world have recommended that such estimates should be used in association with serum creatinine. In adults, several such equations have been widely used, including the Cockcroft and Gault equation, the Modification of Diet in Renal Disease (MDRD) Study equations, and the CKD-EPI equations.

The Cockcroft and Gault equation is one of the earliest of these equations (see Table 21.2). It remains widely used in the context of assessing drug dosages for patients with kidney impairment (see later). However, the requirement for the measurement of body weight, the lack of a version validated for standardized creatinine assays, and the availability of demonstrably better equations have limited its ongoing use.

The era of GFR estimation as a widely used simple clinical tool began with publication of the MDRD Study equation in 1999, followed by its abbreviated four variable (creatinine, age, gender, race [black/white]) form in 2000. The original MDRD equation was updated in 2006 to a version suitable for IDMS traceable creatinine assays and this was widely endorsed by national organizations. Generally, the MDRD equation was found to provide a more accurate assessment of GFR than the Cockcroft and Gault equation, with the important advantage

of not requiring knowledge of weight, allowing automatic reporting of eGFR with the results for serum creatinine.

In 2009 the Chronic Kidney Disease Epidemiology Collaboration described a further equation (CKD-EPI_{creat}), again based on serum creatinine, gender, race, and age (see Table 21.2). This equation showed some improvement over MDRD, especially at higher levels of GFR (>60 mL/min per 1.73 m²). KDIGO have recommended that the CKD-EPI_{creat} equation should be used to estimate GFR.

Because the relationship between creatinine and kidney function varies among individuals, disease conditions, and populations, no GFR equation to date has found universal applicability. This remains an intense area of ongoing research. Other equations that have been developed are the CKD-EPI equations based on cystatin C, either alone or in combination with creatinine, and the Berlin Initiative Study (BIS) Group published equations with claimed superior performance in older people (see Table 21.2).

The relationship between creatinine and GFR has been shown to vary between some ethnicities, presumably due to differences in muscularity and dietary pattern. For example, the MDRD and CKD-EPI_{creat} equation publications showed a clear distinction between African American and non-African Americans. The requirement to adjust GFR estimating equations for race is a potential limitation to their global application and local implementation.

Limitations to creatinine-based GFR estimating equations include interferences in creatinine measurement and patient-specific factors. Any factor affecting creatinine measurement, such as bias, imprecision, drug effects, hemolysis, icterus, or lipemia, will directly affect the eGFR. Any relevant way in which a patient is different from those included in the trials to establish

the equations will also affect the accuracy of the equation at an individual level. These include patients with AKI, in whom serum creatinine concentrations may change rapidly and with extremes of muscularity (e.g., bodybuilders, amputees, and people with muscle wasting disorders). The equations are also not suitable for patients on dialysis and for use during pregnancy; adult equations should not be used with patients under 18 years of age. Notwithstanding this, in general, equations improve the estimation of GFR compared with serum creatinine alone.

Reference Intervals

An average GFR in young healthy individuals is 110 mL/min per 1.73 m² (5th to 95th percentiles approximately 90 to 140 mL/min per 1.73 m²) with a gradual fall with increasing age. The age-related changes are also seen in outputs of eGFR equations. Age-related reference intervals are not widely used in clinical medicine with decision points based on CKD staging or advice for drug dosing providing the usual clinical support.

Glomerular Filtration Rate Measurement and Estimation: Future Considerations

Evaluation of kidney function remains an essential component of medical practice, and much has been achieved in recent years to improve and standardize estimates of GFR. However, there remains room for improvement, and research into new and better markers, equations, and procedures for the measurement of kidney function will continue. The challenge to the clinical lab is to use the best available tools in a coordinated manner so that evidence-based clinical decisions can be made. One particular focus should be collaboration between laboratories so that patients and doctors obtain the same clinical information irrespective the laboratory selected.

REVIEW QUESTIONS

- The plasma concentration of creatinine is maintained within narrow limits predominantly by:
 - the constant catabolism of purines.
 - the constant rate of protein metabolism.
 - the glomerular filtration rate.
 - an individual's diet.
- Symptoms of gout are caused by:
 - decreased renal perfusion as in heart failure.
 - precipitation of excessive uric acid in joints and the urinary tract.
 - a low-protein diet.
 - liver dysfunction as in hepatitis.
- The main nitrogen-containing compound that accounts for more than 75% of excreted nonprotein nitrogen is:
 - uric acid.
 - creatinine.
 - creatinine.
 - urea.
- A deficiency of the enzyme xanthine oxidase due to severe hepatocellular disease will lead to:
 - increased urea concentration.
 - decreased creatinine concentration.
 - hypouricemia.
 - hyperuricemia.
- During protein breakdown, the amino acid nitrogen groups are converted to urea through the urea cycle in which of the following?
 - Liver
 - Kidneys
 - Heart
 - GI tract
- Compensated Jaffe assays for creatinine assessment:
 - add a fixed value to the assay result to compensate for interferants.
 - subtract a fixed value from each result to compensate for noncreatinine interference.
 - use a special formula that involves body mass and urine production to "normalize" creatinine results.
 - involve averaging of values to remove possible discrepancies between two samples obtained at different times of the day.

7. A value of 8.4 mg/dL of urea converts to what in mmol/L?
 - a. 2.99
 - b. 29.9
 - c. 3.92
 - d. 39.2
8. Ascorbic acid and bilirubin are interferants in which of the following assays?
 - a. Jaffe reaction and uricase methods
 - b. Jaffe reaction only
 - c. Jaffe reaction, urease methods, and uricase methods
 - d. Urease methods only
9. In the uricase method of uric acid measurement, the main interferants that must be minimized are:
 - a. phenol and bilirubin.
 - b. ascorbic acid and bilirubin.
 - c. endogenous ammonia and oxidizing agents.
 - d. ketone bodies and protein.
10. Uric acid is:
 - a. the major product of protein catabolism.
 - b. a derivative of muscle creatine.
 - c. a metabolite of urinary nitrogen.
 - d. the major product of purine catabolism.

Carbohydrates

David B. Sacks

OBJECTIVES

1. Define the following:
Carbohydrate
Gluconeogenesis
Glycogen
Glycogen storage disease
Glycogenesis
Glycogenolysis
Glycolysis
Glycoprotein
Hypoglycemia
Ketone
Monosaccharide, disaccharide, and polysaccharide
2. Provide two examples each of a monosaccharide, a disaccharide, and a polysaccharide; describe the chemical structure of each.
3. Summarize the regulation of glucose concentration in the blood, including two hormones involved in this process.
4. Explain the relationship between glucose, lactate, and pyruvate.
5. Discuss the brain's dependence on glucose, including how the brain is affected in a hypoglycemic state and the alternative energy source used.
6. State the blood glucose concentration at which hypoglycemia is typically diagnosed.
7. List three causes of fasting hypoglycemia and three causes of postprandial (nonfasting) hypoglycemia; describe the 72-hour fast test for diagnosing hypoglycemia.
8. List two causes of hypoglycemia in persons with type 1 diabetes.
9. Compare glucose values in fasting whole-blood, capillary, and venous blood specimens; state the reasons for the discrepant values.
10. State the effects of glycolysis on glucose in whole blood; list two ways in which glycolysis can be inhibited.
11. Describe the hexokinase method for measurement of glucose in blood; state the specimen requirements and the principle of the reaction, and list the known interferences.
12. Describe the glucose oxidase method for measurement of glucose in blood; state the specimen requirements and the principle of the reaction, and list the known interferences.
13. Describe the chemical reaction used to assess lactate concentration in blood; describe the chemical reaction used to assess pyruvate concentrations in blood.
14. State the specimen collection and storage requirements for blood lactate and pyruvate analyses.
15. Analyze and resolve case studies regarding carbohydrate disorders; correlate the results of carbohydrate analysis with carbohydrate disorders.

KEYWORDS AND DEFINITIONS

Aldehyde An organic compound with a carbonyl group (a carbon atom double-bonded to an oxygen) at the end of the carbon chain bonded to hydrogen and an R group (usually an alkyl group).

Carbohydrate Aldehyde or ketone derivatives of polyhydroxy alcohols composed of carbon, hydrogen, and oxygen in a ratio of 1:2:1.

Cori cycle The mechanism by which lactate produced by muscles is carried to the liver, converted back to glucose via gluconeogenesis, and returned to the muscles.

Diabetes mellitus A group of metabolic disorders of carbohydrate metabolism in which glucose is underutilized, producing hyperglycemia.

Glucagon A protein hormone that maintains blood glucose concentration by increasing blood glucose through glycogenolysis.

Glucose A six-carbon monosaccharide derived from the breakdown of carbohydrates in the diet or in body stores; can also be endogenously synthesized from protein or the glycerol moiety of triglycerides.

Glycogen An extensively branched polysaccharide containing many glucose residues and found particularly in muscle and liver cells for glucose storage.

Hypoglycemia Blood glucose concentration in the blood decreased below a healthy reference interval.

Insulin A protein hormone that maintains blood glucose concentration by decreasing blood glucose through cellular uptake.

Ketone An aldehyde that has a carbonyl group (carbon atom double-bonded to an oxygen atom) at any position other than at the end of the carbon chain.

Lactate An intermediary product in glucose metabolism that accumulates in the blood predominantly when tissue oxygenation is decreased, as during strenuous exercise; an increased blood lactate concentration is called lactic acidosis.

Pyruvate An organic acid formed from glucose through glycolysis.

Carbohydrates, including sugar and starch, are widely distributed in plants and animals. They perform multiple functions, such as serving as structural components in RNA and DNA (ribose and deoxyribose sugars) and providing a source of energy (glucose). Glucose is derived from (1) the breakdown of carbohydrates in the diet (grains, starchy vegetables, and legumes) or in body stores (glycogen), and (2) endogenous synthesis from protein or from the glycerol moiety of triglycerides. When energy intake exceeds expenditure, the excess is converted to fat and glycogen for storage in adipose tissue and liver or muscle, respectively. When energy expenditure exceeds caloric intake, endogenous glucose formation occurs from the breakdown of carbohydrate stores and from noncarbohydrate sources (e.g., amino acids, lactate, glycerol).

The glucose concentration in the blood is maintained within a fairly narrow interval under diverse conditions (feeding, fasting, or severe exercise) by hormones such as **insulin**, **glucagon**, and epinephrine (see details in [Chapter 33](#)). Measurement of glucose is one of the most commonly performed procedures in hospitals and other health care chemistry laboratories, and glucose measurement by point-of-care and home-use meters is a multi-billion-dollar industry. The most frequently encountered disorder of carbohydrate metabolism is high blood glucose concentration due to **diabetes mellitus**, which affects approximately 9% of the US adult population. The incidence of hypoglycemia (low blood glucose) is unknown but is low (excluding patients who use exogenous insulin to control blood glucose).

any other position, a **ketone** is formed ([Fig. 22.1](#)). The simplest carbohydrate is glycol aldehyde, the aldehyde derivative of ethylene glycol. The aldehyde and ketone derivatives of glycerol are, respectively, glyceraldehyde and dihydroxyacetone (see [Fig. 22.1](#)). Monosaccharides are termed *aldoses* and *ketoses* according to the position of the carbonyl group ([Fig. 22.2](#)).

Compounds that are identical in composition and differ only in spatial configuration are called *stereoisomers*. The carbon atoms in the unbranched chain are numbered 1 to 6, as shown by the numbers at the left of the formula for D-glucose in [Fig. 22.2](#). The designation D- or L- refers to the position of the hydroxyl group on the carbon atom adjacent to the last (bottom) CH₂OH group. In general, designations of D- and L- for a sugar molecule refer to the stereoisomeric forms of the highest-numbered asymmetrical carbon atom.* By convention, the D-sugars are written with the hydroxyl group on the right, and the L-sugars are written with the hydroxyl group on the left (see [Fig. 22.2](#)). Most sugars in the human body are of the D-configuration. Several different structures exist, depending on the relative positions of the hydroxyl groups on the carbon atoms.

Fig. 22.1 Three-carbon carbohydrates.

CHEMISTRY OF CARBOHYDRATES

Carbohydrates are aldehyde or ketone derivatives of polyhydroxy (more than one –OH group) alcohols or compounds that yield these derivatives on hydrolysis.

Monosaccharides

A monosaccharide is a simple sugar that consists of a single polyhydroxy aldehyde or ketone unit and is unable to be hydrolyzed to a simpler form. The backbone is made up of several carbon atoms. Sugars containing three, four, five, six, and seven carbon atoms are known as *trioses*, *tetroses*, *pentoses*, *hexoses*, and *heptoses*, respectively. One of the carbon atoms is double-bonded to an oxygen atom to form a carbonyl group. An **aldehyde** has the carbonyl group at the end of the carbon chain, whereas if the carbonyl group is at

Fig. 22.2 Typical six-carbon sugars.

*Although the D and L designations are used in this chapter, readers should be aware that in the Cahn-Ingold-Prelog system, a series of rules determine configurations. In this new system, the symbols R and S are used to designate configurations.

The formula for glucose can be written in the form of aldehyde or enol, a short-lived reactive species. Shift to the enol anion is favored in alkaline solution, as follows:

The presence of a double bond and a negative charge in the enol anion makes glucose an active reducing substance that is oxidized by relatively mild oxidizing agents, such as cupric and ferric ions. Glucose in hot alkaline solution readily reduces cupric ions to cuprous ions. The color change has been used as a presumptive indication for the presence of glucose; for many years, blood and urine glucose concentrations were measured this way. Some other sugars also reduce cupric ions in alkaline solution; these are collectively referred to as *reducing sugars*.

The aldehyde group reacts with the hydroxyl group on carbon 5, represented by a symmetrical ring structure and depicted by the Haworth formula, in which glucose is considered as having the same basic structure as pyran (Fig. 22.3). In this formula, the plane of the ring is considered to be perpendicular to the plane of the paper, with the heavy lines pointing toward the reader. Hydroxyl groups in position 1 are then below the plane (α -configuration) or above the plane (β -configuration). A six-member ring sugar containing five carbons and one oxygen is a derivative of pyran and is called

a *pyranose*. When linkage occurs with formation of a five-member ring containing four carbons and one oxygen, the sugar has the same basic structure as furan and is called a *furanose*. Fructose is shown in two cyclical forms. Fructopyranose is the configuration of the free sugar, and fructofuranose occurs whenever fructose exists in combination with disaccharides and polysaccharides, as in sucrose and inulin.

Disaccharides

Two monosaccharides join covalently by an O-glycosidic bond, with loss of a molecule of water, to form a disaccharide. The chemical bond between the sugars always involves the aldehyde or ketone group of one monosaccharide joined to an alcohol group (e.g., maltose) or an aldehyde or ketone group (e.g., sucrose) of the other monosaccharide (Fig. 22.4). The most common disaccharides are as follows:

Maltose = glucose + glucose
 Lactose = glucose + galactose
 Sucrose = glucose + fructose

If the linkage between two monosaccharides is between the aldehyde or ketone group of one molecule and a hydroxyl group of another molecule (as in maltose and lactose), one potentially free ketone or aldehyde group remains on the second monosaccharide. Consequently, the second glucose residue can be oxidized and is capable of existing in α - or β -pyranose form. Thus the disaccharide is a reducing sugar, but its reducing power is only approximately 40% of

Fig. 22.3 The Haworth formula for sugars.

Fig. 22.4 Structural formulas of disaccharides.

the reducing power of the two single monosaccharides added together. Alternatively, if the linkage between two monosaccharides involves the aldehyde or ketone groups of both molecules (as in sucrose), a nonreducing sugar is formed because no free aldehyde or ketone group remains.

Polysaccharides

The linkage of multiple monosaccharide units results in the formation of polysaccharides. The major storage carbohydrates are starch in plants and glycogen in animals, both of which form granules inside cells. Polysaccharides can provide structural support. Cellulose is used by plants, whereas chitin is the principal component of the exoskeleton of arthropods (insects and crustacea).

Starch and Glycogen

Most starches are composed of a mixture of amyloses and amylopectins. Amylose consists of one long unbranched chain of glucose units linked together by α -1,4-linkages, with only the terminal aldehyde group free. In amylopectin, most of the units are joined by α -1,4-links, but α -1,6-glycosidic bonds also exist every 24 to 30 residues, producing sidechains. Amylopectin contains up to 1 million glucose residues. The structure of **glycogen** is similar to that of amylopectin, but branching is more extensive and is evident every 8 to 12 glucose residues. These branches enhance the solubility of glycogen and allow the glucose residues to be more readily mobilized. Glycogen is most abundant in the liver and is also found in skeletal muscle. The difference in structure between amylose and amylopectin is important in selection of the appropriate starch substrate for amylase determinations (see [Chapter 19](#)). The rate of hydrolysis is affected by structural differences in the starch.

Cellulose

Cellulose is an important structural polysaccharide in plants. It is an unbranched polymer of glucose residues joined by β -1,4-linkages. The β -configuration facilitates the formation of long straight chains, producing fibers of high tensile strength. The β -1,4-linkages are not hydrolyzed by α -amylases. Because humans do not have cellulases, they are unable to digest vegetable fiber.

Glycoproteins

Many integral membrane proteins have oligosaccharides covalently attached to the extracellular region, forming glycoproteins. In addition, most proteins that are secreted, such as antibodies, hormones, and coagulation factors, are glycoproteins. The number of attached carbohydrate residues varies among proteins and constitutes 1% to 70% of the weight of the glycoprotein. The oligosaccharides are attached by *O*-glycosidic linkages to the sidechain oxygen of serine or threonine residues or by *N*-glycosidic linkages to the sidechain nitrogen of asparagine residues.

One of the biological functions of the carbohydrate chains is to regulate the life span of proteins. Loss of sialic acid residues from the ends of oligosaccharide chains on erythrocytes

results in the removal of red blood cells from the circulation. Carbohydrates have also been implicated in cell-cell recognition, in secretion, and in targeting of proteins to specific subcellular domains.

BIOCHEMISTRY AND PHYSIOLOGY

Glucose is the primary energy source for the human body. After absorption (see [Chapter 38](#)), the metabolism of all hexoses proceeds according to the body's requirements. This metabolism results in (1) energy production by conversion to carbon dioxide and water, (2) storage as glycogen in the liver or as triglyceride in adipose tissue, or (3) conversion to keto acids, amino acids, or protein.

The complete picture of intermediary metabolism of carbohydrates is complex and is interwoven with the metabolism of lipids and amino acids. For details, readers should consult a biochemistry textbook.

Regulation of Blood Glucose Concentration

The concentration of glucose in the blood is regulated by a complex interplay of multiple pathways, modulated by several hormones. *Glycogenesis* is the name for the conversion of glucose to glycogen, the most important storage polysaccharide in liver and muscle. The reverse process, namely, the breakdown of glycogen to glucose and other intermediate products, is termed *glycogenolysis*. The formation of glucose from noncarbohydrate sources, such as amino acids, glycerol, or lactate, is termed *gluconeogenesis*. The conversion of glucose or other hexoses into lactate or pyruvate is called *glycolysis*. Further oxidation to carbon dioxide and water occurs through the Krebs (citric acid) cycle and the mitochondrial electron transport chain coupled to oxidative phosphorylation, which generates the adenosine triphosphate that provides chemical energy for many bodily processes. Oxidation of glucose to carbon dioxide and water also occurs through the hexose monophosphate shunt pathway, which produces the reduced form of nicotinamide-adenine dinucleotide phosphate.

Hypoglycemia

Hypoglycemia is a blood glucose concentration below the fasting value, but the definition of a specific limit is difficult. The most widely used cutoff is 50 mg/dL (2.8 mmol/L), but some authors suggest 60 mg/dL (3.3 mmol/L). A transient decline may occur 1.5 to 2 hours after a meal, and it is not uncommon for plasma glucose concentration as low as 50 mg/dL (2.8 mmol/L) to be observed 2 hours after ingestion of an oral glucose load. Similarly, extremely low fasting blood glucose values may be occasionally noted without symptoms or evidence of underlying disease. Hypoglycemia is rare in persons who do not have drug-treated diabetes mellitus.

Symptoms of hypoglycemia vary among individuals, and none is specific. Epinephrine produces the classic signs and symptoms of hypoglycemia, namely, trembling, sweating, nausea, rapid pulse, light-headedness, hunger, and epigastric discomfort. These autonomic symptoms are nonspecific and

may be noted in other conditions, such as hyperthyroidism, pheochromocytoma, or even anxiety. Although controversial, some investigators have proposed that a rapid decrease in blood glucose concentrations may trigger the symptoms even though the blood glucose itself may not reach hypoglycemic values, whereas gradual onset to a similar glucose concentration may not produce symptoms.

The brain is completely dependent on blood glucose for energy production under physiological conditions, and approximately half of the glucose used in resting adults is in the central nervous system (CNS). Very low concentrations of plasma glucose (<20 or 30 mg/dL; 1.1 mmol/L or 1.7 mmol/L) cause severe CNS dysfunction. During prolonged fasting or hypoglycemia, ketones may be used as an energy source. The broad spectrum of symptoms and signs of CNS dysfunction range from headache, confusion, blurred vision, and dizziness, to seizures, loss of consciousness, and even death; these symptoms are known as *neuroglycopenia*. Restoration of plasma glucose usually produces prompt recovery, but irreversible damage may occur.

The age of onset of hypoglycemia is a convenient way to classify the disorder, but some overlap occurs among the various groups. For example, some glycogen storage disorders may arise in the third decade of life, and hormone deficiencies may occur in childhood.

Hypoglycemia in Neonates and Infants

Neonatal blood glucose concentrations are much lower than those of adults (mean, ~35 mg/dL; 1.9 mmol/L) and decline shortly after birth when liver glycogen stores are depleted. Glucose concentrations as low as 30 mg/dL (1.7 mmol/L) in a term infant and 20 mg/dL (1.1 mmol/L) in a premature infant may occur without clinical evidence of hypoglycemia. The more common causes of hypoglycemia in the neonatal period include prematurity, maternal diabetes, gestational diabetes mellitus (GDM), and maternal toxemia/preeclampsia. These are usually transient. Hypoglycemia with onset in early infancy is usually less transitory and may be due to inborn errors of metabolism or ketotic hypoglycemia; this type of hypoglycemia usually develops after fasting or a febrile illness.

Fasting Hypoglycemia in Adults

Hypoglycemia results from a decreased rate of hepatic glucose production or an increased rate of glucose use. Symptoms suggestive of hypoglycemia are fairly common, but hypoglycemic disorders are rare. However, true hypoglycemia usually indicates serious underlying disease and may be life threatening. An exact threshold for the establishment of hypoglycemia is not always possible, and values as low as 30 mg/dL (1.7 mmol/L) may be encountered in healthy, premenopausal women during the classic test—a 72-hour fast. Symptoms usually begin at plasma glucose concentrations below 55 mg/dL (3 mmol/L), and impairment of cerebral function begins when glucose is less than 50 mg/dL (2.8 mmol/L).

The 72-hour fast should be conducted in a hospital. During the fast, the patient should be allowed a liberal intake

of calorie-free and caffeine-free fluids. Samples typically are drawn every 6 hours for analysis of plasma glucose, insulin, C-peptide, and proinsulin. When plasma glucose concentration is 60 mg/dL (3.3 mmol/L) or less, analyses are performed every 1 to 2 hours. The fast should be concluded when plasma glucose concentration falls to a predetermined concentration (such as 45 mg/dL [2.5 mmol/L] or less) or the patient exhibits signs or symptoms of hypoglycemia, or after 72 hours. Most patients with true hypoglycemia show an abnormally low value within 12 hours of beginning a fast. Women exhibit significantly lower glucose concentrations than men. Low plasma glucose alone is not sufficient to establish the diagnosis, and the absence of signs or symptoms of hypoglycemia during the fast excludes the diagnosis of a hypoglycemic disorder as the cause of such symptoms.

More than 100 causes of hypoglycemia have been reported. Drugs are the most prevalent cause, and many widely used drugs, including propranolol, salicylates, and disopyramide, produce hypoglycemia. Oral hypoglycemic agents, which have long half-lives (35 hours for chlorpropamide), are the most frequent cause of drug-induced hypoglycemia and may be directly measured in blood or urine. Surreptitious administration of insulin is detected by the discovery of low C-peptide concentrations with increased insulin concentrations.

Ethanol produces hypoglycemia by inhibiting gluconeogenesis, and this inhibition is aggravated by malnutrition (low glycogen stores) in individuals with chronic alcoholism. Individuals with hepatic failure (e.g., viral hepatitis, ingestions of toxins) have impaired gluconeogenesis or glycogen storage, which may result in hypoglycemia. Decreased hepatic glucose production requires dysfunction of more than 80% of the liver. Deficiencies of growth hormone (especially with coexistent adrenocorticotrophic hormone [ACTH] deficiency), glucocorticoids, thyroid hormone, or glucagon may also produce hypoglycemia. Although a deficiency of glucocorticoids (e.g., Addison disease) is most consistently associated with hypoglycemia, most glucocorticoid-deficient adults are not hypoglycemic. Hormonal deficiency causes hypoglycemia in children more frequently than in adults.

Demonstration of a low plasma glucose concentration in the presence of a high plasma insulin value is highly suggestive of an insulin-producing pancreatic islet cell tumor. Because healthy people exhibit a wide range of insulin concentrations, absolute hyperinsulinemia occurs in less than 50% of individuals with insulinomas. Serum insulin concentrations inappropriately high for concurrent plasma glucose values denote autonomous insulin secretion. Provocative tests (glucagon, tolbutamide, or calcium) or suppression tests (infusion of insulin and measurement of C-peptide), although strongly recommended in the past, generally are not necessary.

Nonpancreatic neoplasms that cause hypoglycemia are rare, but when present, they are often extremely large mesenchymal neoplasms. No single mechanism explains the hypoglycemia in all cases, but secretion of a precursor of insulin-like growth factor 2 is the most commonly encountered finding. Glucose utilization is increased, especially in muscle, presumably reflecting activity of the hormone.

Hypoglycemia caused by septicemia should be relatively easy to diagnose. The mechanism is not well defined, but depleted glycogen stores, impaired gluconeogenesis, and increased peripheral use of glucose may all be contributing factors. Glucose tolerance is commonly depressed in individuals with renal disease, and hypoglycemia may occur in those with end-stage renal failure.

Some of the conditions that produce fasting hypoglycemia are readily apparent, but others require a lengthy diagnostic workup. Once fasting hypoglycemia is demonstrated, specific tests should be performed to establish the underlying cause. The oral glucose tolerance test (OGTT) is not an appropriate study for evaluation of a patient suspected of having hypoglycemia.

Postprandial Hypoglycemia

Drugs, antibodies to insulin or the insulin receptor, inborn errors (e.g., fructose-1,6-diphosphatase deficiency), and *reactive hypoglycemia* (also referred to as *functional hypoglycemia*) produce hypoglycemia in the postprandial (fed) state. It has been proposed that for individuals with vague symptoms after food ingestion, the preferred terminology should be *idiopathic reactive hypoglycemia* or *idiopathic postprandial syndrome*.

At the Third International Symposium on Hypoglycemia, reactive hypoglycemia was defined as a “clinical disorder in which the patient has postprandial symptoms suggesting hypoglycemia that occur in everyday life and are accompanied by a blood glucose concentration less than 45 to 50 mg/dL (2.5–2.8 mmol/L) as determined by a specific glucose measurement on arterialized venous or capillary blood, respectively.” Patients complain of autonomic symptoms that occur approximately 1 to 3 hours after eating and seem to obtain relief, lasting 30 to 45 minutes, by food intake. These symptoms are rarely due to low blood glucose concentrations. A 5- or 6-hour glucose tolerance test had been the standard procedure to establish the presence of postprandial hypoglycemia, but that has been discredited. Consequently, an OGTT *should not be used in the diagnosis of reactive hypoglycemia*.

Postprandial hypoglycemia is infrequent, and demonstration of hypoglycemia during spontaneously occurring symptomatic episodes is necessary to establish the diagnosis. If this is not possible, a 5-hour meal tolerance test (which simulates the composition of a normal diet) or a “hyperglucidic” (high-glucose) breakfast test has been proposed.

The diagnosis of hypoglycemia has also been used to explain a wide variety of disorders that appear unrelated to blood glucose abnormalities. These nonspecific symptoms include fatigue, muscle spasms, palpitations, numbness, tingling, pain, sweating, mental dullness, sleepiness, weakness, and fainting. Behavioral abnormalities, poor school performance, and delinquency have been incorrectly attributed to low blood glucose concentrations. A diagnosis of hypoglycemia should not be made unless a patient meets the criteria of *Whipple's triad of low blood glucose concentration*: (1) symptoms known or likely to be caused by hypoglycemia, (2) low glucose measured when symptoms occur, and

(3) relief of symptoms when glucose is increased to normal. Demonstration of normal plasma glucose concentration when the patient exhibits symptoms excludes the possibility of a hypoglycemic disorder.

Hypoglycemia in Diabetes Mellitus

Hypoglycemia occurs frequently in individuals with type 1 or type 2 diabetes. Patients using insulin experience approximately one to two episodes of symptomatic hypoglycemia per week, and severe hypoglycemia that requires assistance from others or is associated with loss of consciousness affects about 10% of this population per year. In patients practicing intensive insulin therapy (e.g., multiple injections, continuous subcutaneous insulin infusion), these figures are increased twofold to sixfold. The chief adverse event associated with intensive therapy in the Diabetes Control and Complications Trial (DCCT) was a threefold increase in the incidence of severe hypoglycemia. Similarly, hypoglycemia occurs in patients with type 2 diabetes (caused by oral hypoglycemic agents or insulin) but is less frequent than in type 1 diabetes. Defective glucose counterregulation (ability to increase glucose, counter to the effect of insulin) and ignorance of hypoglycemia are two pathophysiological mechanisms that contribute to hypoglycemia in patients with diabetes.

Defective Glucose Counterregulation Counterregulatory responses become impaired in patients with type 1 diabetes, increasing the risk of hypoglycemia. The secretion of glucagon in response to hypoglycemia is impaired by an unknown mechanism early in the course of type 1 diabetes. The secretory response of epinephrine to hypoglycemia becomes deficient later in the course of the disease. These defects are selective because other stimuli continue to elicit glucagon and epinephrine secretion. Glucose counterregulation does not appear to be notably defective in patients with type 2 diabetes.

Hypoglycemia Unawareness Up to 50% of patients with long-standing (longer than 30 years) type 1 diabetes do not experience neurogenic warning symptoms and are prone to more severe hypoglycemia. The mechanism is thought to be associated with a decreased epinephrine response to hypoglycemia. Intensively treated patients with type 1 diabetes require lower plasma glucose concentrations to elicit symptoms of hypoglycemia. Some authors have claimed that therapeutic use of human insulin rather than other insulins results in an increased incidence of ignorance of hypoglycemia, but analysis of 45 studies revealed no significant differences in hypoglycemic episodes among insulin species.

Lactate and Pyruvate

Lactic acid, an intermediary in carbohydrate metabolism, is predominantly derived from white skeletal muscle, brain, skin, renal medulla, and erythrocytes. The blood lactate concentration depends on the rate of production in these tissues and the rate of metabolism in the liver and kidneys. The liver uses approximately 65% (75 g/d) of the total basal lactate produced, predominantly in gluconeogenesis. The **Cori cycle** is the conversion of glucose to **lactate** in the periphery and reconversion of lactate to glucose in the liver. Extrahepatic

removal of lactate occurs by oxidation in red skeletal muscle and the renal cortex. A moderate increase in lactate production results in increased hepatic lactate clearance, but uptake by the liver is saturable when concentrations exceed 18 mg/dL (2 mmol/L). During strenuous exercise, for example, lactate concentrations may increase significantly, from an average concentration of about 8 mg/dL (0.9 mmol/L) to more than 180 mg/dL (20 mmol/L) within 10 seconds. No concentration of lactate is uniformly accepted for the diagnosis of lactic acidosis, but lactate concentrations exceeding 45 mg/dL (5 mmol/L) with pH less than 7.25 indicate significant lactic acidosis.

Measurement of **pyruvate** is useful in the evaluation of patients with inborn errors of metabolism who have increased serum lactate concentrations. A lactate-to-pyruvate ratio of less than 25 suggests a defect in gluconeogenesis, whereas an increased ratio (≥ 35) indicates reduced intracellular conditions found in hypoxia. Inborn errors associated with an increased lactate-to-pyruvate ratio include pyruvate carboxylase deficiency and defects in oxidative phosphorylation. Pyruvate is also measured in clinical studies evaluating reperfusion after myocardial ischemia.

Lactic Acidosis

Lactic acidosis occurs in two clinical settings: (1) type A (hypoxic), associated with decreased tissue oxygenation, such as shock, hypovolemia, and left ventricular failure; and (2) type B (metabolic), associated with disease (e.g., diabetes mellitus, neoplasia, liver disease), drugs/toxins (e.g., ethanol, methanol, salicylates), or inborn errors of metabolism. Lactic acidosis is not uncommon and occurs in approximately 1% of those admitted to the hospital. It has a mortality rate greater than 60%, which approaches 100% if hypotension is also present. Type A is much more common.

The mechanism of type B lactic acidosis is not known but is speculated to be a primary defect in mitochondrial function with impaired oxygen use. This leads to reduced stores of adenosine triphosphate (ATP) and nicotinamide adenine dinucleotide (NAD^+), with accumulation of NADH and H^+ . In the presence of decreased liver perfusion or liver disease, lactate removal from the blood is reduced, thereby aggravating the lactic acidosis.

An uncommon but often undiagnosed cause of lactic acidosis is D-lactic acidosis. Absorption and accumulation of D-lactate from abnormal intestinal bacteria may cause systemic acidosis. This condition occurs after jejunoileal bypass surgery and manifests as altered mental status (from mild drowsiness to coma) with increased blood concentrations of D-lactate. Virtually all the commonly used laboratory assays for lactate use L-lactate dehydrogenase, which does not detect D-lactate. D-Lactate can be measured by gas-liquid chromatography or, enzymatically, with a specific D-lactate dehydrogenase.

Lactate in cerebrospinal fluid (CSF) normally parallels blood concentrations. With biochemical alterations in the CNS, however, CSF lactate values change independently of blood values. Increased CSF concentrations are noted in

individuals with cerebrovascular accidents, intracranial hemorrhage, bacterial meningitis, epilepsy, and other CNS disorders. In aseptic (viral) meningitis, lactate concentrations in CSF are not usually increased; hence, CSF lactate has been used to help discriminate between viral and bacterial meningitis, but the clinical utility has been questioned. In a few children with inherited metabolic disease, CSF lactate concentrations may be increased despite plasma lactate in the reference interval.

Inborn Errors of Carbohydrate Metabolism

Deficiency or absence of an enzyme that participates in carbohydrate metabolism may result in accumulation of monosaccharides, which can be measured in the urine. Most of these conditions are inherited as autosomal recessive traits. Sugars frequently appear in the urine as a result of excessive consumption, without the presence of underlying disease.

Techniques used to separate and identify sugars have included fermentation, optical rotation, osazone formation with phenylhydrazine, specific chemical tests, and paper or thin-layer chromatography. The availability of glucose oxidase test strips, specific for glucose, has greatly simplified the differentiation of glucose from other reducing substances. For practical purposes, the urinary sugars of clinical interest are glucose and galactose. Urine from infants and children should be tested by both the glucose oxidase and copper reduction tests to identify individuals with inborn errors of metabolism. Reducing substances other than glucose should be further identified by chromatographic procedures.

Glycogen Storage Disease

Glycogen, although present in most tissues, is stored predominantly in the liver and skeletal muscle. During fasting, liver glycogen is converted to glucose to provide energy for the whole body. In contrast, skeletal muscle lacks glucose-6-phosphatase, and muscle glycogen can be used only locally for energy. Glycogen storage disease is a generic name encompassing at least 12 rare inherited disorders of glycogen storage in tissues. The different forms of glycogen storage disease are categorized by numerical type in the chronological sequence in which these defects were identified. Each form is due to a deficiency of a specific enzyme in glycogen metabolism, producing a quantitative or a qualitative defect of glycogen storage. Numerous mutations have been identified in patients with these conditions.

Because both the liver and skeletal muscle have the highest rates of glycogen metabolism, these tissues are most affected. The liver forms (types I, III, IV, VI, and IX), which comprise approximately 80% of the total, are marked by hepatomegaly (due to increased liver glycogen stores) and hypoglycemia (caused by inability to convert glycogen to glucose). Hypoglycemia is manifested by autonomic clinical symptoms (sweating, shakiness, and a light-headed feeling), growth retardation, and laboratory findings of decreased insulin and increased glucagon concentrations in the blood. The muscle forms (types II, V, and VII), in contrast, have mild symptoms

that usually appear in young adulthood during strenuous exercise as a result of the inability to provide energy for muscle contraction. Other muscle disorders may exhibit similar symptoms but are readily differentiated through evaluation of glycogen stores. The specific diagnosis of each type is made directly by demonstrating the enzyme defect in tissue.

ANALYTICAL METHODOLOGY

Analytical methods for measuring glucose, ketone bodies, lactate, and pyruvate are discussed in this section. Methods for measuring insulin, proinsulin, and glucagon are discussed in Chapter 33.

Measurement of Glucose in Body Fluids

Several methods are used to measure glucose in blood, serum, plasma, and urine. The College of American Pathologists (CAP) surveys demonstrate that all methods exhibit a coefficient of variation (CV) among laboratories that is $\leq 2.6\%$ for glucose values on lyophilized serum.

Specimen Collection and Storage

In individuals with a normal hematocrit, fasting whole-blood glucose concentration is approximately 10% to 12% lower than plasma glucose. Although the glucose concentrations in the water phase of red blood cells and plasma are similar (the erythrocyte plasma membrane is freely permeable to glucose), the water content of plasma (93%) is approximately 11% greater than that of whole blood at a normal hematocrit. In most clinical laboratories, plasma or serum is used for most glucose determinations; methods for self-monitoring of glucose use whole-blood samples but may measure the glucose concentration in the plasma phase. During fasting, capillary blood glucose concentration is only 2 to 5 mg/dL (0.1 mmol/L to 0.3 mmol/L) higher than that of venous blood. After a glucose load, however, capillary blood glucose concentrations are 20 to 70 mg/dL (1.0 to 3.9 mmol/L; mean, ≈ 30 mg/dL [1.7 mmol/L]; equivalent to 20% to 25%) higher than the concentrations in concurrently drawn venous blood samples, probably due to glucose consumption in the tissues.

Glycolysis decreases serum glucose by approximately 5% to 7% in 1 hour (5 to 10 mg/dL; 0.3 mmol/L to 0.6 mmol/L) in normal uncentrifuged coagulated blood at room temperature. The rate of *in vitro* glycolysis is higher in the presence of leukocytosis or bacterial contamination. In separated, non-hemolyzed sterile serum, the glucose concentration is generally stable as long as 8 hours at 25°C and up to 72 hours at 4°C; variable stability is observed with longer storage periods. Plasma, removed from the cells after moderate centrifugation, contains leukocytes that also metabolize glucose—although cell-free sterile plasma has no glycolytic activity.

Sodium fluoride or, less commonly, sodium iodoacetate, is used to inhibit glycolysis. Fluoride ions prevent glycolysis by inhibiting enolase, an enzyme that requires Mg^{2+} . Inhibition is due to the formation of an ionic complex consisting of Mg^{2+} , inorganic phosphate, and fluoride ions; this complex interferes with the interaction of enzyme and substrate.

Fluoride is also a weak anticoagulant because it binds calcium; however, clotting may occur after several hours, and it is therefore advisable to use a *combined fluoride-oxalate mixture*, such as 2 mg of potassium oxalate ($K_2C_2O_4$) and 2 mg of NaF/mL of blood, to prevent late clotting. Other anticoagulants (e.g., ethylenediaminetetraacetic acid, citrate, heparin) can also be used. Fluoride ions in high concentration inhibit the activity of urease and certain other enzymes; consequently the specimens may be unsuitable for determination of urea in procedures that require urease and for direct assay of some serum enzymes. $K_2C_2O_4$ causes loss of cell water, thereby diluting the plasma. Samples collected in these tubes therefore should not be used for measurement of other analytes.

Although fluoride has been widely used to inhibit glycolysis, the rate of decline in the first 1 to 2 hours after sample collection is not altered, and glycolysis may continue at a slower rate for up to 4 hours. Acidification of blood using citrate buffer inhibits *in vitro* glycolysis more effectively than fluoride.

To minimize glycolysis, the cells should be removed within minutes. Alternatively, the tube should be placed in an ice-water slurry and the cells separated within 30 minutes. Neither of these approaches is practical in routine analysis. It may not be necessary in routine analysis to use a fluoride-containing tube if plasma is separated from cells or if glucose is measured within 30 minutes of blood collection. However, inhibitors of glycolysis are necessary in patients with greatly increased leukocyte counts because differences of up to 65 mg/dL (3.6 mmol/L) have been observed between glucose values with and without glycolytic inhibitors after 1 to 2 hours of contact with the blood cells.

CSF may be contaminated with bacteria or other cells and should be analyzed immediately for glucose. If a delay in measurement is unavoidable, the sample should be centrifuged and stored at 4°C or -20°C .

In 24-hour collections of urine, glucose may be preserved by adding 5 mL of glacial acetic acid to the container before starting the collection. The final pH of the urine is usually between 4 and 5, which inhibits bacterial activity. Other preservatives that have been proposed include 5 g of sodium benzoate per 24-hour specimen, or chlorhexidine and 0.1% sodium nitrate with 0.01% benzethonium chloride. These may be inadequate, and urine should be stored at 4°C during collection. Urine samples may lose as much as 40% of their glucose after 24 hours at room temperature.

Measurement of Glucose in Blood

Hexokinase (HK), or glucose oxidase, is widely used in assays to measure the concentration of glucose in body fluids.

Hexokinase Methods. HK methods are based on a coupled enzyme assay that uses HK and glucose-6-phosphate dehydrogenase:

As indicated, glucose is first phosphorylated by ATP in the presence of HK and Mg^{2+} . The glucose-6-phosphate formed is oxidized by G6PD to 6-phosphogluconate in the presence of $NADP^+$ or NAD^+ . The amount of reduced NADP (NADPH) or NADH produced is directly proportional to the amount of glucose in the sample and is measured by the increase in absorbance at 340 nm. $NADP^+$ is the cofactor when G6PD derived from yeast is used in the assay; NAD^+ is the cofactor when bacterial (*Leuconostoc mesenteroides*) G6PD is used. A reference method based on this principle has been developed and validated. In the reference method, serum or plasma is deproteinated by the addition of solutions of barium hydroxide and zinc sulfate. The clear supernatant is mixed with a reagent containing ATP, NAD^+ , HK, and G6PD, incubated at 25°C until the reaction is complete, and NADH is measured. Calibrators and blanks are carried through the entire procedure, including the deproteination step.

Although highly accurate and precise, the reference method is too exacting and time-consuming for routine use in a clinical laboratory. An alternative approach is to apply the reaction directly to serum or plasma and use a specimen blank to correct for interfering substances that absorb at 340 nm.

Serum or plasma may be used. Sodium fluoride (NaF), with an anticoagulant such as ethylenediaminetetraacetic acid (EDTA), heparin, oxalate, or citrate, may be used. Hemolyzed specimens containing more than 0.5 g of hemoglobin/dL are unsatisfactory because phosphate esters and enzymes released from red blood cells interfere with the assay. Other sources of interference include drugs, bilirubin, and lipemia (triglycerides of 500 mg/dL [~ 5.7 mmol/L] or greater causing a positive interference).

Absorbances of sample or calibrator reaction mixtures are measured after the reactions have continued to completion (steady-state reaction, "end-point" method) or at a fixed time after initiation of the reaction (fixed-time kinetics). In the steady state, end-point methods for glucose concentrations may be calculated directly, based on the molar absorptivity of NADPH or NADH, but inclusion of a set of calibrators is recommended to detect possible deterioration of enzymes, ATP, $NADP^+$, or NAD^+ —all of which are unstable. Reagents may also contain substances that react with the coenzymes. The presence of these substances is evaluated by measurement of the increase in absorbance observed in a reagent blank. The highest calibrator provides a check on the linearity of the response and the adequacy of the enzyme reagent. The procedures typically show a linear relation between absorbance and glucose concentrations of 0 to 500 mg/dL (0 to 28 mmol/L). Serum or plasma samples with glucose concentrations that exceed 500 mg/dL (28 mmol/L) should be diluted (usually with isotonic saline) and reassayed.

Also available are HK procedures in which indicator reactions produce colored products, enabling absorbance measurements in the visible range. An oxidation reduction system containing phenazine methosulfate and a substituted tetrazolium compound, 2-(*p*-iodophenyl)-3-*p*-nitrophenyl-5-phenyltetrazolium chloride (INT), is reacted with NADPH formed in the reaction. The reduced INT is colored, with maximal absorbance at 520 nm.

Glucose Oxidase Methods. Glucose oxidase catalyzes the oxidation of glucose to gluconic acid and hydrogen peroxide:

Addition of the enzyme peroxidase and a chromogenic oxygen acceptor, such as *o*-dianisidine, results in the formation of a colored compound that is measured:

Glucose oxidase is highly specific for β -D-glucose. Because 36% and 64% of glucose in solution is in the α - and β -forms, respectively, complete reaction requires mutarotation of the α -form to the β -form. Some commercial preparations of glucose oxidase contain an enzyme, mutarotase, which accelerates this reaction. Otherwise, extended incubation time allows spontaneous conversion.

The second step, involving peroxidase, is much less specific than the glucose oxidase reaction. Various substances, such as uric acid, ascorbic acid, bilirubin, hemoglobin, tetracycline, and glutathione, inhibit the reaction (presumably by competing with the chromogen for H_2O_2), producing lower values. Some glucose oxidase preparations contain catalase as a contaminant; catalase activity decomposes peroxide and decreases the intensity of the final color obtained. Calibrators and unknowns should be simultaneously analyzed under conditions in which the rate of oxidation is proportional to the glucose concentration.

Glucose oxidase methods are suitable for measurement of glucose in CSF. Urine, however, contains high concentrations of substances (such as uric acid) that interfere with the peroxidase reaction, producing falsely low results. Therefore, the glucose oxidase method should not be used for urine. A method in which the urine is first pretreated with an ion exchange resin to remove interfering substances has been described.

Some instruments use a polarographic oxygen electrode that measures the rate of oxygen consumption after the sample is added to a solution containing glucose oxidase. Because this measurement involves only the glucose oxidase reaction, interferences encountered in the peroxidase step are eliminated. To prevent formation of oxygen from H_2O_2 by catalase present in some preparations of glucose oxidase, H_2O_2 is removed by two additional reactions:

The latter reaction is effective even when catalase activity has diminished on storage of reagents. The procedure has been applied directly to urine, serum, plasma, or CSF. However, this approach should not be used for determination of glucose in whole blood because blood cells consume oxygen.

In dry, multilayer, slide automated systems, glucose is measured by a glucose oxidase procedure. A 10- μ L sample of serum, plasma, urine, or CSF is placed on a porous film

on top of the layer containing the reagents. Glucose diffuses through the film and reacts with the reagents to produce a colored end product or dye. The intensity of this dye is measured through a lower transparent film by reflectance spectrophotometry. Advantages include small sample size, no liquid reagents, and improved stability on storage.

Glucose Dehydrogenase Method. The enzyme glucose dehydrogenase (β -D-glucose: NAD oxidoreductase, EC 1.1.1.47) catalyzes the oxidation of glucose to gluconolactone with concomitant reduction of NAD^+ to NADH. Mutarotase is added to shorten the time necessary to reach equilibrium. The amount of NADH generated is proportional to the glucose concentration. The reaction appears to be highly specific for glucose, shows no interference from common anticoagulants and substances normally found in serum, and provides results in close agreement with HK procedures. The glucose dehydrogenase procedure is not widely used in the United States, except in a glucose meter.

Measurement of Glucose in Urine

Examination of urine for glucose is rapid, inexpensive, and noninvasive and has been used to screen large numbers of samples. Monitoring of urine glucose lacks sensitivity and specificity and provides no information about blood glucose concentrations below the renal threshold (usually 180 mg/dL; 10 mmol/L). Older screening tests detect all sugars that reduce copper. Unfortunately, these tests also react with reducing substances other than glucose. Qualitative, quantitative, and semiquantitative methods are widely available for measuring glucose in urine and have essentially replaced the nonspecific tests in adults. Note that a reducing sugar method other than an enzymatic method for glucose must be used when neonates or infants are screened for inborn errors of metabolism that result in the appearance of reducing sugars other than glucose (e.g., galactose, fructose) in the urine.

Qualitative Method for Measurement of Total Reducing Substances. Benedict qualitative reagent contains cupric ion complexed to citrate in alkaline solution. Reducing substances convert cupric to cuprous ions, forming yellow cuprous hydroxide or red cuprous oxide. A convenient adaptation of the procedure marketed in tablet form (Clinitest) has been discontinued.

Semiquantitative Measurement of Glucose in Urine. Convenient paper test strips are commercially available from several manufacturers. Examples are Clinistix, Diastix, and Chemstrip. All use the glucose-specific enzyme glucose oxidase in a chromogenic assay. For example, Clinistix has filter paper impregnated with glucose oxidase, peroxidase, and the dye *o*-toluidine. Other dyes, such as tetramethylbenzidine, can be used. The test end of the strip is moistened with freshly voided urine and is examined after 10 seconds. A blue color develops if glucose is present at a concentration of 100 mg/dL or greater. Results are read by comparing the test color with a standard color chart. Automated urinalysis systems capable of analyzing 300 strips per hour are commercially available. The test is more sensitive for glucose than is the copper reduction test (Clinitest), which has a detection limit of 250 mg/dL (~14 mmol/L).

False-positive results may be produced by contamination of urine with H_2O_2 or a strong oxidizing agent, such as hypochlorite (bleach). False negative results may occur with large quantities of reducing substances, such as ketones, ascorbic acid, and salicylates. For routine examinations, a negative result by the strip test is usually interpreted to mean that the urine specimen is negative for glucose.

Other strip tests (such as Keto-Diastix and Diascreen 2GK) are designed for the semiquantitative estimation of both glucose and ketone bodies. The glucose portion of the strip uses the glucose oxidase–peroxidase method. The hydrogen peroxide produced oxidizes iodide to iodine, yielding various intensities of brown that correspond to increasing concentrations of glucose in the urine. The detection limit is 100 mg/dL (5.5 mmol/L).

Quantitative Methods for Determination of Glucose in Urine. Applications of various procedures for quantitative determination of glucose in urine were previously discussed in the section on the determination of glucose in body fluids. HK or glucose dehydrogenase procedures are recommended for greatest accuracy and specificity. Glucose oxidase procedures that depend only on the consumption of oxygen or the production of H_2O_2 are also reliable. Glucose oxidase procedures that include the H_2O_2 -peroxidase reaction are not used for urine.

Reference Intervals

Although glucose is assayed by several different analytical procedures, reference intervals do not vary significantly among methods. The following values are representative of glucose assays:

Sample Reference Intervals for Fasting Glucose

Plasma/Serum

Adults	74–99 mg/dL (4.1–5.5 mmol/L)
Children	60–100 mg/dL (3.5–5.5 mmol/L)
Premature neonates	20–60 mg/dL (1.1–3.3 mmol/L)
Term neonates	30–60 mg/dL (1.7–3.3 mmol/L)
Whole blood	65–95 mg/dL (3.6–5.3 mmol/L)
CSF	40–70 mg/dL (60% of plasma value) (2.2–3.9 mmol/L)

Urine

24 h	1–15 mg/dL (0.1–0.8 mmol/L)
------	-----------------------------

Note that the American Diabetes Association (ADA) criteria of fasting glucose of 126 mg/dL (7.0 mmol/L) or greater—not the reference interval—is used for the diagnosis of diabetes. Moreover, the threshold for diagnosis of hypoglycemia is variable and is considerably less than the lower limit of the reference interval. No sex difference exists. Plasma glucose concentrations increase with age—fasting glucose concentrations increase approximately 2 mg/dL (0.1 mmol/L) per decade; postprandial concentrations increase by 4 mg/dL (0.2 mmol/L) per decade; and concentrations after a glucose challenge increase by 8 to 13 mg/dL (0.4–0.7 mmol/L) per decade.

CSF glucose concentrations should be approximately 60% of the plasma concentrations and must always be compared with concurrently measured plasma glucose for adequate clinical interpretation.

Measurement of Lactate and Pyruvate in Body Fluids

Determination of Lactate in Whole Blood

Lactate is oxidized to pyruvate by lactate dehydrogenase in the presence of NAD^+ . The NADH formed in this reaction is measured spectrophotometrically at 340 nm and serves as a measure of the lactate concentration:

The equilibrium of the reaction normally lies far to the left. However, by buffering the pH between 9.0 and 9.6, adding an excess of NAD^+ , and trapping the reaction product pyruvate with hydrazine, the equilibrium can be shifted to the right. Pyruvate can also be removed through reaction with L-glutamate in the presence of alanine aminotransferase.

Because of its high specificity and simplicity, the enzymatic method is the method of choice for the measurement of lactate, although other methods may also be used (e.g., gas chromatography).

The Vitros analyzer, formerly the Ektachem, uses an assay in which lactic acid is oxidized to pyruvate by lactate oxidase. The H_2O_2 generated oxidizes a chromogen system, and the absorbance of the resulting dye complex, measured spectrophotometrically at 540 nm, is directly proportional to the lactate concentration in the specimen. Each mole of lactate that is oxidized produces 0.5 mol of dye complex.

Specimen Collection and Storage. Careful techniques are necessary to prevent changes in lactate concentration while blood is drawn and afterward. Patients should be fasting and at complete rest for at least 2 hours to allow lactate concentrations to reach steady state.

Venous specimens should be obtained without the use of a tourniquet or immediately after the tourniquet has been applied. Alternatively, the tourniquet should be removed after the puncture has been performed, and the blood should be allowed to flow for several minutes before the sample is withdrawn. Arterial blood sampling, which prevents these potential pitfalls, may also be used. Patients should avoid exercise of the hand or arm immediately before and during the procedure.

Both venous and arterial blood may be collected in heparinized syringes and immediately delivered into a premeasured amount of chilled protein precipitant, such as trichloroacetic acid, metaphosphoric acid, or perchloric acid. The clear supernatant, after centrifugation, is stable at 4°C for as long as 8 days. Meticulous attention to sample preparation is required. If blood is not preserved as directed, lactate rapidly increases in blood as a result of glycolysis. Increases may be as great as 20% within 3 minutes and 70% within 30

minutes at 25°C . Specimens collected as described in this section are also suitable for determination of pyruvate.

If a plasma specimen is required, blood should be collected in a tube containing 10 mg of NaF and 2 mg of $\text{K}_2\text{C}_2\text{O}_4$ per milliliter of blood. Ideally, the specimen should be immediately cooled, and the cells separated within 15 minutes, but reasonable stability of volunteers' lactate is seen at room temperature for 30 minutes in whole blood with NaF. Once the plasma is separated from the cells, lactate is stable.

Reference Intervals. The reference intervals for lactate in adults are as follows:

Specimen	LACTATE	
	mmol/L	mg/dL
Venous Blood		
At rest	0.3–2.0	2.7–18
Arterial Blood		
At rest	0.3–1.5	2.7–13.5

Laboratories should verify that these ranges are appropriate for use in their own settings.

Individuals in the hospital exhibit a wider range of values. Lactic acidosis occurs with blood lactate concentrations exceeding 5 mmol/L (45 mg/dL). Severe exercise dramatically increases lactate concentrations, and even movement of leg muscles by individuals at bed rest may result in significant increases. Plasma values are about 7% higher than those in whole blood, although differences depend on the procedure used. CSF values are usually similar to blood concentrations but may change independently in CNS disorders. Age-related reference intervals for CSF lactate (and lactate-to-pyruvate ratios) have been established in children. The upper limit of the reference interval (90th percentile) for CSF lactate in children in hospital from birth to 15.5 years varies continuously from 16 to 17 mg/dL (1.78 to 1.88 mmol/L). Normal 24-hour urine output of lactate is 5.5 to 22 mmol/dL.

Determination of Pyruvate in Whole Blood

The reaction involved in the determination of pyruvate is essentially the reverse of the reaction used in the lactate procedure:

At about pH 7.5, the equilibrium constant strongly favors the reaction to the right. The method is very specific, and 2-oxoglutarate, oxaloacetate, acetoacetate, and β -hydroxybutyrate do not interfere as with colorimetric methods. Pyruvate is extremely unstable in blood, more so than lactate; immediate use of a chilled protein precipitant is recommended.

Fasting venous blood, drawn when the individual is at rest, has a pyruvate concentration of 0.3 to 0.9 mg/dL (0.03 to 0.10 mmol/L). Arterial blood contains 0.2 to 0.7 mg/

dL (0.02 to 0.08 mmol/L). Values for CSF are 0.5 to 1.7 mg/dL (0.06 to 0.19 mmol/L). Urine output of pyruvate is normally 1 mmol/dL or less. Few clinical indications warrant the measurement of blood or urine pyruvate concentrations.

Measurement of Ketones in Body Fluids

Measurement of ketones in urine and blood is widely performed in patients with diabetes for both diagnosis and monitoring of diabetic ketoacidosis (see more details in the sixth edition of the *Tietz Textbook of Clinical Chemistry and Molecular Diagnostics*). None of the commonly used methods for the detection and determination of ketone bodies in serum or urine reacts with all three ketone bodies. The Gerhardt ferric chloride test reacts with acetoacetate only. Tests using nitroprusside are at least 10 times more sensitive to acetoacetate than to acetone and give no reaction at all with β -hydroxybutyrate. Traditional tests for β -hydroxybutyrate are indirect; they require brief boiling of the urine to remove acetone and acetoacetate by evaporation (acetoacetate first breaks down spontaneously to acetone), followed by gentle oxidation of β -hydroxybutyrate to acetoacetate and acetone with peroxide, ferric ions, or dichromate. The acetoacetate thus formed may be detected with the Gerhardt test or by one of the procedures in which nitroprusside is used. Quantitative enzymatic assays for β -hydroxybutyrate that can be performed directly on blood or serum are commercially available.

The semiquantitative Acetest and Ketostix are frequently used but are insensitive to β -hydroxybutyrate. It is important to bear in mind, therefore, that a negative nitroprusside test result does not rule out ketoacidosis.

Acetest

Acetest tablets contain a mixture of glycine, sodium nitroprusside, disodium phosphate, and lactose. Acetoacetate or acetone (to a lesser extent) in the presence of glycine forms a lavender-purple complex with nitroprusside. β -Hydroxybutyrate

does not react with nitroprusside. Disodium phosphate provides an optimum pH for the reaction, and lactose enhances the color.

Ketostix

Ketostix is a modification of the nitroprusside test, in which a reagent strip is used instead of a tablet. The Ketostix test gives a positive reaction within 15 seconds with a specimen containing at least 50 mg of acetoacetate per liter. The color chart from the manufacturer gives readings for ketone concentrations of 50, 150, 400, 800, and 1600 mg/L. Acetone also reacts, but the test is less sensitive to it.

Determination of β -Hydroxybutyrate

In this test, β -hydroxybutyrate in the presence of NAD^+ is converted by β -hydroxybutyrate dehydrogenase to acetoacetate, producing reduced NAD (NADH). Diaphorase catalyzes the reduction of nitroblue tetrazolium (NBT) by NADH to produce a purple compound, and its absorbance is read in a special meter that provides a digital readout.

Serum β -hydroxybutyrate values vary from 0.21 to 2.81 mg/dL (0.02 to 0.27 mmol/L) in healthy people after an overnight fast. Ketone bodies in the blood can reach 20 mg/dL (2 mmol/L) with prolonged exercise. Patients with diabetic ketoacidosis usually have β -hydroxybutyrate concentrations greater than 20 mg/dL (>2 mmol/L).

Determination of Ketone Bodies in Urine

Acetest, Ketostix, Ketosis Test Strips, and Trueplus Ketone Test Strips are suitable for detecting ketone bodies in urine. The sensitivity and specificity of these tests are the same as outlined for serum.

POINTS TO REMEMBER

Disorders of Glucose Homeostasis

Hyperglycemia (increased blood glucose concentration), caused by diabetes mellitus, is the most frequently encountered disorder of carbohydrate metabolism.

Hypoglycemia is a blood glucose concentration below the fasting value.

The symptoms of hypoglycemia vary among individuals and none is specific.

Symptoms suggestive of hypoglycemia are fairly common, but true hypoglycemia is rare in individuals who do not have drug-treated diabetes mellitus.

Hypoglycemia occurs frequently in patients with diabetes and is the limiting factor in glycemic management.

True hypoglycemia usually indicates serious underlying disease.

Measurement of Glucose

Measurement of glucose is one of the most commonly performed analytical procedures.

Glucose may be measured in blood, urine, or cerebrospinal fluid.

Almost all common methods are enzymatic.

The glucose concentration in whole blood is 10%–12% lower than the plasma glucose concentration.

Glycolysis occurs in whole blood in a test tube and delay in separating cells from plasma (or serum) can significantly decrease the glucose concentration.

REVIEW QUESTIONS

- The formation of glucose from noncarbohydrate sources occurs mostly in the liver and is referred to as:
 - gluconeogenesis.
 - glycogenesis.
 - glycolysis.
 - glycogenolysis.
- Which of the following hormones decreases blood glucose?
 - Epinephrine
 - Glucagon
 - Cortisol
 - Insulin
- Which anticoagulant is considered the best for serum glucose analysis because it inhibits glycolysis?
 - Sodium oxalate
 - EDTA
 - Sodium fluoride
 - Heparin
- An example of a disaccharide is:
 - glucose.
 - starch.
 - lactose.
 - fructose.
- The conversion of glucose into its storage form is referred to as:
 - glycogenesis.
 - glycolysis.
 - glycogenolysis.
 - glyconeogenesis.
- Which of the following statements concerning carbohydrates is *incorrect*?
 - Individuals diagnosed with type 1 diabetes mellitus can display hypoglycemic symptoms because of the impairment of glucagon secretion.
 - Ethanol produces hypoglycemia by inhibiting gluconeogenesis.
 - Monosaccharides are formed from the breakdown of starches and disaccharides within the small intestine.
 - The brain functions normally with a low concentration of plasma glucose (<20 to 30 mg/dL).
- The formation of 6-phosphogluconate with concomitant production of NADH is the final step in which of the following coupled-enzyme assays for glucose?
 - Hexokinase method
 - Glucose oxidase method
 - Glucose dehydrogenase method
 - Polarographic method
- The typical cause of an inborn error of carbohydrate metabolism is:
 - lack of insulin production.
 - glucagonoma.
 - absence of an enzyme involved in carbohydrate metabolism.
 - chronic alcoholism with hepatic failure.
- The most widely used cutoff blood glucose concentration that indicates hypoglycemia is:
 - 100 mg/dL.
 - 75 mg/dL.
 - 50 mg/dL.
 - 25 mg/dL.
- Deficiency of a specific enzyme involved in glycogen metabolism will produce some type of:
 - glycogen storage disease.
 - lactic acidosis.
 - insulin deficiency.
 - glycolysis.

Lipids, Lipoproteins, Apolipoproteins, and Other Cardiac Risk Factors

Sridevi Devaraj, Alan T. Remaley

OBJECTIVES

1. Define the following terms:
 - Apolipoprotein
 - Atherosclerosis
 - Cholesterol
 - Cholesterol ester
 - Emulsification
 - Fatty acid
 - Glycerol
 - Ketone bodies
 - Lipid
 - Lipoprotein
 - Lipoprotein lipase
 - Phospholipid
 - Prostaglandin
 - Sphingolipid
 - Triglyceride
2. List and describe the six classes of lipids, based on chemical structure and function.
3. Discuss the metabolism of cholesterol, fatty acids, and triglycerides, including biochemical structure, synthesis, esterification, absorption, and catabolism.
4. Compare and contrast the six lipoprotein classes on the basis of their physical characteristics, functions, and clinical significance; list the major apolipoproteins that are carried by these lipoproteins and their functions.
5. Describe the exogenous, endogenous, intracellular cholesterol transport, and reverse cholesterol transport pathways of lipoprotein metabolism, including the following:
 - Function
 - Lipoproteins and apolipoproteins involved
 - Enzymes involved
 - Cells/cellular components and organs involved
6. State the effects that the following disorders have on lipid metabolism, lipoproteins, apolipoproteins, and laboratory lipid values, and state known genetic defect:
 - Lipoprotein lipase deficiency
 - Type V hyperlipoproteinemia
 - Dysbetalipoproteinemia
 - Familial hypercholesterolemia
 - Familial combined hyperlipidemia
 - Familial hypertriglyceridemia
 - Familial defective apolipoprotein B-100
 - Hypoalphalipoproteinemia disorders
7. List five major risk factors for coronary heart disease; describe how lipoprotein disorders are managed in adults and children, including therapeutic lifestyle changes and use of cholesterol and triglyceride-lowering agents.
8. List five specific causes of secondary hyperlipidemia/dyslipoproteinemia, including examples of exogenous, endocrine, storage, and renal disorders.
9. Diagram the typical enzymatic reactions used in the laboratory to measure cholesterol and triglyceride; state specimen requirements and describe current assays used to assess the following analytes:
 - HDL
 - LDL
 - Apolipoprotein A-I and B-100
 - Lipoprotein(a)
10. State the uses for and the calculation of the Friedewald formula; calculate low-density lipoprotein cholesterol using this formula when given appropriate information.
11. Describe high-sensitivity C-reactive protein (CRP) and its measurement, and state its usefulness in predicting coronary heart disease events.
12. Analyze and solve case studies related to disorders of lipids and lipoproteins.

KEYWORDS AND DEFINITIONS

Acylglycerol (glycerol ester) A three-carbon alcohol that contains a hydroxyl group on each of its carbons and is classified by the number of fatty acyl groups present; triglycerides are the predominant form of glycerol ester in plasma.

Apolipoproteins The major protein components of lipoproteins.

Atherosclerosis A pathogenic process that is the underlying cause of the common cardiovascular disorders of (1) myocardial infarction, (2) cerebrovascular disease, and (3) peripheral vascular disease.

Cholesterol A steroid alcohol with 27 carbon atoms arranged in a tetracyclic sterane ring system, with a carbon–hydrogen (C–H) side chain and a polar hydroxyl group on its A-ring, making it an amphipathic molecule.

Coronary heart disease A narrowing of the small blood vessels caused by atherosclerotic plaque that impairs the supply of blood and oxygen to the heart.

Fatty acid Any straight-chain monocarboxylic acid with an alkyl chain generally classed as saturated fatty acids with no double bonds; monounsaturated fatty acids with one double bond; and polyunsaturated fatty acids—those with multiple double bonds.

Lipids A class of compounds that are soluble in organic solvents but are nearly insoluble in water and contain nonpolar carbon–hydrogen bonds.

Lipoprotein(a) A lipoprotein structurally similar to low-density lipoprotein but containing a plasminogen-like protein called apo(a). It carries only a relatively small

fraction of total cholesterol but is considered to be particularly proatherogenic.

Lipoproteins Spherical micelle-like particles involved in the transport of lipids with nonpolar neutral lipids (triglycerides and cholesterol esters) in their core and more polar amphipathic lipids (phospholipids and free cholesterol) at their surface.

Phospholipid A polar amphipathic lipid located on the surface of a lipoprotein; phospholipids are also found at the aqueous interface of biologic membranes.

Prostaglandin Potent signaling molecules derived from unsaturated 20-carbon fatty acids (primarily arachidonic acid) via the cyclooxygenase pathway; these compounds are involved in a wide variety of physiological processes.

Triglyceride A glycerol ester consisting of three molecules of fatty acid esterified to glycerol and constituting 95% of tissue storage fat.

Lipids have important roles in virtually all aspects of life, including (1) serving as hormones, (2) serving as an energy source, (3) assisting digestion, and (4) acting as structural components in cell membranes. In addition, lipids and **lipoproteins**, the particles that transport lipids in the blood, are intimately involved in the development of **atherosclerosis**—a common disorder that occurs when fat, cholesterol, and other substances build up in the walls of arteries and form atherosclerotic plaques in the vessel wall. Atherosclerosis is the underlying cause of the common cardiovascular disorders of (1) myocardial infarction, (2) cerebrovascular disease, and (3) peripheral vascular disease. In this chapter, the basic biochemistry, clinical significance, and laboratory analysis of each of the major lipid and lipoprotein classes and other cardiovascular risk factors are discussed.

BASIC LIPIDS

The term *lipid* applies to a class of compounds that are soluble in organic solvents but nearly insoluble in water. Lipids primarily contain nonpolar carbon–hydrogen (C–H) bonds and typically yield **fatty acids** and/or complex alcohols after hydrolysis. Some lipids also contain charged or polar groups, which makes these lipids amphipathic with affinity for both water and organic solvents. Amphipathic lipids, such as **phospholipids**, are found at the aqueous interface of biologic membranes because they can form lipid bilayers. Most phospholipids contain a diglyceride, a phosphate group, and a simple organic molecule, such as choline, as the head group. One exception to this rule is sphingomyelin, which is derived from sphingosine instead of glycerol. Overall, lipids are broadly subdivided into six groups on the basis of their chemical structure, namely, (1) cholesterol, (2) fatty acids, (3) acylglycerols, (4) sphingolipids, (5) prostaglandins, and (6) terpenes.

Cholesterol

Cholesterol is found almost exclusively in animals and is a key membrane component of all cells. It is a steroid alcohol with 27 carbon atoms arranged in a tetracyclic sterane ring system, with a C–H side chain (Fig. 23.1). Although it is relatively hydrophobic, cholesterol does contain a polar hydroxyl (OH) group on its A-ring (see Fig. 23.1), thus making it amphipathic (i.e., possessing both hydrophilic and lipophilic properties) and accounting for surface orientation in cell membranes.

Cholesterol Absorption

The average Western diet contains approximately 300 to 450 mg of cholesterol per day, which is derived mostly from animal and dairy products, but only 30% to 60% of it is absorbed. Any dietary esterified cholesterol that contains a fatty acid attached to the hydroxyl group on the A-ring is rapidly hydrolyzed in the intestine to free cholesterol and fatty acids by cholesterol esterases secreted from the pancreas and the small intestine.

Before it is absorbed, cholesterol is first solubilized through a process called emulsification, which involves the formation of mixed micelles that contain (1) unesterified cholesterol, (2) fatty acids, (3) monoglycerides, (4) phospholipids, and (5) conjugated bile acids. Bile acids, by acting as detergents, are the most critical factor in micelle formation. Increased amounts of fat favor the absorption of cholesterol by the formation of more micelles. Most cholesterol absorption occurs in the middle jejunum and the terminal ileum of the small intestine and is mediated by the enterocyte protein NPC1L1 (Niemann-Pick C1-like 1), which is the target for the drug ezetimibe that blocks cholesterol absorption. Once cholesterol enters the intestinal mucosal cell, it is packaged with **triglycerides**, phospholipids, and a large protein called **apolipoprotein** (apo) B-48 into large lipoprotein particles called chylomicrons. Chylomicrons are secreted into the lymph

Fig. 23.1 Structure of cholesterol.

Fig. 23.2 Cholesterol biosynthesis (stage 1).

and eventually enter the circulation, where they deliver the absorbed dietary lipid to the liver and peripheral tissues.

Cholesterol Synthesis

Cholesterol is synthesized by all cells in the body, but particularly by the liver and the intestine. The biosynthesis of cholesterol occurs in three stages. In the first stage (Fig. 23.2), acetyl coenzyme A (CoA), a key metabolic intermediate, forms the six-carbon thioester 3-hydroxy-3-methyl-glutaryl (HMG)-CoA. In the second stage (Fig. 23.3), HMG-CoA is reduced to

mevalonate and then is decarboxylated to a series of five-carbon isoprene units. These isoprene units are condensed to form first a 10-carbon (geranyl pyrophosphate) and then a 15-carbon intermediate (farnesyl pyrophosphate). Two of these C_{15} molecules then combine to produce the final product of the second stage, squalene, a 30-carbon acyclic hydrocarbon. The second stage is important because it contains the step involving the microsomal enzyme HMG-CoA reductase, which is the rate-limiting enzyme in cholesterol biosynthesis; it is inhibited by statins, the most effective class of current cholesterol-lowering drugs. The third stage (Fig. 23.4) occurs in the endoplasmic reticulum, with many of the intermediate products bound to a specific carrier protein. In a series of oxidation-decarboxylation reactions, a number of side chains are removed from the tetracyclic sterane ring structure to form the 27-carbon molecule of cholesterol.

Cholesterol Esterification

Cholesterol is esterified to a fatty acid to form a cholesteryl ester by two different enzymes. In cells, excess cholesterol is esterified by acylcholesterol acyltransferase (ACAT) (Fig. 23.5), which helps reduce the cytotoxicity of excess free cholesterol. Once esterified, cholesteryl esters are stored in intracellular lipid drops. Cholesteryl esters also are formed in the circulation by the action of a plasma enzyme called lecithin cholesterol acyltransferase (LCAT), which is bound to lipoproteins, particularly high-density lipoproteins (HDLs). The reaction involves the transfer of a fatty acid from the second carbon position of phosphatidylcholine (lecithin) to cholesterol (see Fig. 23.5). Cholesteryl esters account for approximately 70% of the total cholesterol in plasma. Once cholesterol is esterified, it loses its free hydroxyl group and becomes much more hydrophobic, moving from the surface of lipoprotein particles to the hydrophobic core.

Cholesterol Catabolism

Except for specialized endocrine cells that use cholesterol for the synthesis of steroid hormones, most peripheral cells have limited ability to further catabolize cholesterol. Cholesteryl esters are hydrolyzed to free cholesterol by various lipases in all cells, but thereafter cholesterol has to be returned to the liver to undergo any further catabolism. Approximately one-third of the daily production of cholesterol, or approximately 400 mg/day, is converted in the liver into bile acids (Fig. 23.6). Approximately 90% of these bile acids are reabsorbed in the lower third of the ileum and are returned to the liver by the enterohepatic circulation. Bile acids that enter the large intestine are partially deconjugated by bacterial enzymes to secondary bile acids. Cholic acid is converted, for example, to deoxycholic acid, and chenodeoxycholic acid is converted to lithocholic acid.

Not all cholesterol delivered to the liver is converted to bile salts. Much of it is resecreted into the circulation on lipoproteins, and the remainder is directly excreted into the bile unchanged, where it is solubilized into mixed micelles by bile acids and phospholipids. When the amount of cholesterol in bile exceeds the capacity of these solubilizing agents, it is possible for cholesterol to precipitate and form gallstones.

Stage 2

Fig. 23.3 Cholesterol biosynthesis (stage 2).

Fatty Acids

RCOOH is the general chemical formula for a fatty acid, where “R” is an alkyl chain. Fatty acid chain lengths vary and are commonly classified as short-chain (2 to 4 carbon atoms), medium-chain (6 to 10 carbon atoms), or long-chain (12 to 26 carbon atoms) fatty acids. Those of importance in human nutrition and metabolism are included in the long-chain class and contain an even number of carbon atoms.

Fatty acids are further classified according to their degree of saturation. Saturated fatty acids have no double bonds (C=C) between their carbon atoms; monounsaturated fatty acids contain one double bond; and polyunsaturated fatty acids contain multiple double bonds (Fig. 23.7). The double

bonds in polyunsaturated fatty acids are usually three carbon atoms apart. Fatty acids from fish, such as salmon, possess up to six unsaturated double bonds and can be more than 20 carbon atoms long. Unsaturated fatty acids are prone to oxidation by the nonenzymatic reaction of oxygen with their double bonds. Numbering of the carbon atoms in fatty acids is done from the carboxyl terminal end (Δ -numbering system) or from the methyl terminal end (η - or ω -numbering system; Table 23.1). In addition, carbon atoms may be labeled with Greek symbols, with α being adjacent to the carboxyl group and ω being farthest away. In the Δ -system, fatty acids are abbreviated according to the (1) number of carbon atoms, (2) number of double bonds, and (3) position(s) of

Fig. 23.4 Cholesterol biosynthesis (stage 3).

Fig. 23.5 Intracellular and intravascular esterification of cholesterol mediated by acylcholesterol acyltransferase and lecithin cholesterol acyltransferase, respectively. double bond(s). For example, linoleic acid would be written as C₁₈:^{2,12} and contains 18 carbons and two unsaturated bonds between carbons 9 and 10 and carbons 12 and 13. When the η - or ω -system is used, linoleic acid would be abbreviated as C₁₈:2n-6, where only the first carbon forming the unsaturated pair is written. The *Geneva* or *systematic* classification, which is based on their chemical names, is a third common nomenclature system for fatty acids (see Table 23.1).

In saturated fatty acids, the chain is extended and flexible; the carbon atoms rotate freely around their longitudinal axis. However, unsaturated fatty acids have a fixed 30-degree bend in their chains at each double bond. Depending on the plane in which this bend occurs, the *cis* or the *trans* isomer is produced. In mammals, all naturally occurring unsaturated fatty acids are of the *cis* variety. *Trans* fatty acids in our diet come primarily from catalytic hydrogenation in which unsaturated double bonds are chemically reduced to raise their melting point. This process is used to “harden” or solidify fats in the manufacture of certain foods, such as margarine.

Most fatty acids are also synthesized by the body except for essential fatty acids, such as linoleic acid (C₁₈:^{2,12}), which is made only by plants. Linoleic acid is also converted to arachidonic acid, which is a precursor for prostaglandin synthesis.

Fatty acids exist in the circulation in an unesterified or free state, the latter primarily bound to albumin, or in various esterified forms, such as triglycerides, phospholipids, or cholesteryl esters. The free fatty acid carboxyl group has a pK_a of approximately 4.8; thus free fatty acid molecules exist primarily in their ionized forms. The normal concentration of free fatty acids in human plasma is 0.3 to 1.1 mmol/L (8 to 31 mg/dL) and is very sensitive to physiological energy demands and the availability of alternative forms of metabolic fuel, such as glucose. Most of the free fatty acids in the circulation are derived from intracellular lipolysis of triglycerides by adipose tissue.

Fatty Acid Catabolism

Fatty acids are catabolized in the mitochondria and produce energy by a series of reactions known as β -oxidation. This process is repeated to shorten the fatty acid chain by two carbon atoms at a time from the carboxy terminal end of the molecule. For example, one mole of palmitic acid (C₁₆) is converted to eight moles of acetyl CoA. Acetyl CoA does not normally accumulate in the cell but is condensed enzymatically with oxaloacetate, derived largely from carbohydrate metabolism (Fig. 23.8), to yield citrate, a major component of the tricarboxylic acid cycle (Krebs cycle). The Krebs cycle is a common pathway for the final oxidation of nearly all metabolic fuels, whether derived from carbohydrate, fat, or protein, and ultimately results in the production of adenosine triphosphate (ATP), the main energy storage molecule in the body. Triglycerides contain three fatty acid molecules and are therefore a relatively efficient storage form of metabolic energy. Furthermore, energy storage by triglycerides is efficient in terms of space because it does not require any water for hydration, unlike carbohydrates.

Fig. 23.6 Bile acid synthesis.

Ketone Formation

During prolonged starvation, or when carbohydrate metabolism is impaired, as in uncontrolled diabetes mellitus, the formation of acetyl CoA exceeds the supply of oxaloacetate. The resulting acetyl CoA excess is diverted to an alternative pathway in the mitochondria for the formation of (1) acetoacetic acid, (2) β -hydroxybutyric acid, and (3) acetone—the three compounds known collectively as ketone bodies (Fig. 23.9). Therefore ketosis develops from excessive production of acetyl CoA, as the body attempts to obtain necessary energy from stored fat in the absence of an adequate supply of carbohydrate metabolites (see Chapter 22).

Acylglycerols (Glycerol Esters)

Glycerol is a three-carbon alcohol that contains a hydroxyl group on each of its carbon atoms.

The two terminal carbon atoms in the glycerol molecule are chemically equivalent and are designated α and α' . The center carbon is labeled β . A common alternative labeling system uses the numeral 1 for the α -carbon, 2 for the β -carbon, and 3 for the α' -carbon. The class of **acylglycerol** is determined by the number of fatty acyl groups present: (1) one fatty acid—monoacylglycerols (monoglycerides); (2) two fatty acids—diacylglycerols (diglycerides); and (3) three fatty acids—triacylglycerols (triglycerides). For example,

Fig. 23.7 Saturated and unsaturated fatty acids.

TABLE 23.1 Fatty Acids Commonly Found in Human Tissue

Common Name	Systematic Name	Δ -Numbering	$-(\omega)$ Numbering
Lauric	Dodecanoic	12:0	12:0
Myristic	Tetradecanoic	14:0	14:0
Palmitic	Hexadecanoic	16:0	16:0
Palmitoleic	9-Hexadecanoic	16:1 ^a	16:1n-7
Stearic	Octadecanoic	18:0	18:0
Oleic	9-Octadecanoic	18:1 ^a	18:1n-9
Linoleic ^a	9,12-Octadecadienoic	18:2 ^{a,12}	18:2n-6
Linolenic ^a	9,12,15-Octadecatrienoic	18:3 ^{a,12,15}	18:3n-3
Arachidic	Eicosanoic	20:0	20:0
Arachidonic	5,8,11,14-Eicosatetraenoic	20:4 ^{a,8,11,14}	20:4n-6

^aEssential fatty acids.Fig. 23.8 Metabolic relations among intermediates of carbohydrate, fat, and protein metabolism. Note that acetyl-coenzyme A (CoA) is produced from both carbohydrate and fat. The glucogenic amino acids, derived from protein metabolism, enter glycolytic paths as α -keto acids. Ketogenic amino acids enter as acetyl-CoA.

Fig. 23.9 Formation of ketone bodies. CoA, Coenzyme A.

1-monoglyceride indicates that a fatty acid is attached to the α -carbon. This numbering system applies to all acylglycerols, including the phosphoglycerides (Figs. 23.10 and 23.11).

Triglycerides constitute 95% of tissue storage fat and are the predominant form of glyceryl esters found in plasma. The fatty acid residues found in (1) monoglycerides, (2) diglycerides, or (3) triglycerides vary considerably and usually include different combinations of long-chain fatty acids (see Table 23.1). In general, triglycerides from plant sources, such as corn, sunflower, and safflower, tend to be enriched in unsaturated fatty acids and are liquid oils at room temperature. Triglycerides from animals, especially ruminants, tend to have saturated acids and are solids at room temperature.

Dietary triglycerides are digested in the duodenum and are efficiently absorbed in the proximal ileum. Through the action of pancreatic and intestinal lipases and in the presence of bile acids, they are first hydrolyzed to glycerol, monoglycerides, and fatty acids. After absorption, these components of triglycerides are reassembled as triglycerides

in the intestinal epithelial cells and then are packaged with cholesterol and apo B-48 to form chylomicrons. Chylomicrons are secreted into the lymphatic system and eventually reach the circulation. Triglycerides are the main metabolic fuel carried by chylomicrons; they are delivered

to the liver and peripheral cells after they have been hydrolyzed to fatty acids by lipases.

Another major class of acylglycerols includes those containing phosphoric acid at the third (α') carbon atom, which is referred to as phosphoglycerides. In their simplest form, the A group consists of a hydrogen atom and the molecule is called a diacylphosphoglyceride. Usually, the A group contains an alcohol, such as (1) choline, (2) serine, (3) inositol, or (4) ethanolamine. If the A group is choline, for example, the molecule is referred to as phosphatidylcholine (lecithin). Because the types of fatty acid residues R_1 and R_2 are varied, numerous types of phospholipids are formed. These phosphoglycerides are named according to the fatty acid acyl esters attached at C-1 and C-2 of the glycerol. Saturated fatty acids are typically esterified to the C-1 position, whereas polyunsaturated fatty acids are often attached to the C-2 position. In inner mitochondrial membranes, more complex phosphoglycerides, known as cardiolipins, are found. They are derived from two phosphoglyceride molecules joined by a glycerol bridge.

Sphingolipids

Sphingolipids make up a fourth class of lipids derived from the amino alcohol sphingosine (Fig. 23.12). This dihydric 18-carbon alcohol contains an amino group at C-17. A fatty acid containing 18 or more carbon atoms is attached to the amino group through an amide linkage to form *ceramide*. This is an intermediate structure in the formation of (1) sphingomyelin, (2) galactosylceramide, and (3) glucosylceramide (see Fig. 23.12). In addition, the sugar-containing ceramides have a sulfate group that is usually attached to the 2-position of the galactose residue to form the sulfatides. The glycosyl ceramides have additional monosaccharide moieties, such as (1) galactose, (2) *N*-acetylgalactosamine, and (3) *N*-acetylneuraminic acid, to form complex globosides and gangliosides. Gangliosides are especially abundant in the membranes of the gray matter of the brain, whereas glycosphingolipids have a more general role in cell membranes and can also be a source of blood group and tumor antigens.

Prostaglandins

Prostaglandins and related compounds, such as thromboxanes and leukotrienes, are derivatives of fatty acids, primarily arachidonate. These potent bioactive lipids exert diverse physiological actions (Table 23.2) at concentrations as low as 1 $\mu\text{g/L}$. The prostaglandins are a series of C20 unsaturated fatty acids that contain a cyclopentane ring; the parent fatty acid has been given the trivial name prostanoic acid. By convention, prostaglandins are abbreviated PG, with the class designated by a capital letter (A, B, E, F, G, H, and I), followed by a number and in some cases a Greek letter (see Figs. 23.10 and 23.13). The number after the capital letter is usually written as a subscript and is used to designate the number of unsaturated bonds in the PG side chains and not within the ring structure itself. Sixteen naturally occurring prostaglandins have been described (Table 23.3), but only seven, along with two thromboxanes, are commonly found in the body. These are termed primary prostaglandins.

Fig. 23.12 Structures of sphingolipids.

TABLE 23.2 Prostaglandin-Mediated Effects

Site of Action	Physiological Response
Arterial smooth muscle	Alters blood pressure
Uterine muscle	Induces labor, therapeutic abortion
Lower gastrointestinal tract	Increases motility
Bronchial smooth muscle	Causes bronchospasm
Platelets	Increase coagulability
Capillaries	Increase permeability
Stomach	Enhances gastric acid secretion
Adipose tissue	Inhibits triglyceride lipolysis

Although prostaglandins have hormone-like action, they are different from conventional hormones in that they are synthesized at the site of action and are made in almost all tissues. Linoleic acid ($C_{18}:2^{9,12}$) is the precursor of two of the three

20-carbon fatty acids that form prostaglandins; linolenic acid ($C_{18};^{29,12,15}$) is the other precursor. Both of these fatty acids are considered essential because they are not synthesized in the body and therefore must be present in the diet. Once formed, prostaglandins have short-lived effects and are catabolized within seconds. Inactivation of prostaglandin appears to be mediated by two enzymes: 15α -hydroxy-prostaglandin dehydrogenase and Δ^{13} -prostaglandin reductase. Prostaglandins are not stored, but the precursor C_{20} fatty acids are present in tissue attached to the C-2 position of phosphoglycerides.

PG, Prostaglandin.

When prostaglandin synthesis is stimulated, the C_{20} precursor is hydrolyzed from phospholipids by phospholipase A_2 . Release of the C_{20} fatty acid appears to be the rate-limiting step in prostaglandin synthesis and is stimulated by various mediators, such as bradykinin, thrombin, or angiotensin II.

Once released, arachidonic acid follows one of two pathways. The lipoxygenase route produces 12-L-hydroperoxy-5,8,10,14 eicosatetraenoic acid (HPETE); HPETE spontaneously decomposes to 12-L-hydroxy-5,8,10,14 eicosatetraenoic acid (HETE) (see Fig. 23.10). The alternative pathway is mediated by cyclooxygenase (COX) to produce the endoperoxides PGG_2 and PGH_2 . Nonsteroidal antiinflammatory drugs (NSAIDs; such as aspirin, ibuprofen, naproxen, and indomethacin) inhibit the COX enzymes, thereby decreasing prostaglandin synthesis.

PGI_2 , or prostacyclin, is derived from arachidonic acid (see Fig. 23.10) in the vascular endothelium. It has a powerful vasodilatory action, especially on the coronary arteries, and inhibits platelet aggregation. Thromboxane A_2 is synthesized from arachidonic acid but is also produced by platelets. It has the opposite effect of prostacyclin because it stimulates the contraction of arterial smooth muscle and enhances platelet aggregation. It has a half-life of approximately 30 seconds and is rapidly converted to its inactive metabolite, thromboxane B_2 . Thromboxanes are slightly different in structure from the other prostaglandins in that they contain six-sided rings of five carbon atoms and one oxygen atom (Fig. 23.14).

Terpenes

Terpenes are polymers of the five-carbon isoprene unit and include vitamins A, E, and K and the dolichols, which play important roles in protein glycosylation.

LIPOPROTEINS

Lipids synthesized in the liver and in the intestine are transported in the plasma in macromolecular complexes known as lipoproteins. Lipoproteins are typically spherical micelle-like

Fig. 23.14 Structures of thromboxanes.

particles with nonpolar neutral lipids (triglycerides and cholesterol esters) in their core and more polar amphipathic lipids (phospholipids and free cholesterol) at their surface (Fig. 23.15). They also contain one or more specific proteins, called apolipoproteins, on their surface.

Classification

Lipoproteins have different physical and chemical properties (Table 23.4) because they contain different proportions of lipids and proteins (Table 23.5). Traditionally, lipoproteins have been categorized on the basis of differences in their hydrated densities, as determined by ultracentrifugation. These categories include (1) chylomicrons, (2) very-low-density lipoprotein (VLDL), (3) intermediate-density lipoprotein (IDL), (4) low-density lipoprotein (LDL), (5) HDL, and (6) **lipoprotein(a)** [Lp(a)]. In general, the larger lipoproteins contain more core lipids in their core, such as triglycerides, and cholesteryl esters and hence are lighter in density. They also contain a smaller relative percentage of protein. In the fasting

state, most plasma triglycerides are present in VLDL, but 2 to 6 hours after a meal, most triglycerides are transported on chylomicrons. LDL carries approximately 70% of total plasma cholesterol but very little triglyceride (see Table 23.5). HDL typically contains approximately 20% to 30% of plasma cholesterol.

Lp(a) is a distinct class of lipoprotein (Table 23.6) that is structurally related to LDL because both lipoproteins possess one molecule of apo B-100 per particle, with similar lipid compositions. Unlike LDL, Lp(a) also contains a carbohydrate-rich protein called apo(a), which is covalently bound to the apo B-100 through a disulfide linkage. Apo(a) exhibits a significant sequence homology with plasminogen and a high degree of variation in polypeptide chain length (Fig. 23.16). Apo(a) contains a tandem array of a protein motif called a *kringle domain* with different-sized apo(a) molecules (polymorphisms) reflecting the inclusion of variable numbers of kringle 4 type 2 domains. The plasma level of Lp(a) is mostly genetically determined and is relatively invariant and thus does not need to be repeatedly measured. The mechanism is unclear, but Lp(a) is particularly proatherogenic, based on recent genetic studies, and has also been associated with aortic stenosis. There is currently no adequate drug or dietary therapy for lowering Lp(a), but a promising new therapy based on antisense oligonucleotides is being developed.

Lipoproteins can be electrophoretically separated, and this forms the basis for one system of nomenclature. For example, at pH 8.6, HDL migrates with the α -globulins, LDL with the β -globulins, and VLDL and Lp(a) between the α - and β -globulins, in the pre- β -globulin region. IDL forms a broad band between β - and pre- β -globulins. Chylomicrons remain at the application point. Traditionally, lipoprotein classes were referred to by their electrophoretic locations as pre- β -lipoprotein, VLDL; β -lipoprotein, LDL; and α -lipoprotein, HDL. Electrophoresis provided the foundation for an early original phenotypical classification system (types 1 to 5) for familial dyslipidemias (for further discussion on this technique, refer to Chapter 11).

HDL, High-density lipoprotein; *IDL*, intermediate-density lipoprotein; *LCAT*, lecithin cholesterol acyltransferase; *LDL*, low-density lipoprotein; *Lp(a)*, lipoprotein(a); *LPL*, lipoprotein lipase; *VLDL*, very-low-density lipoprotein.

APOLIPOPROTEINS

Apolipoproteins are the major protein components of lipoproteins (see Table 23.6). Each class of lipoprotein carries several apolipoproteins in differing proportions. Apo A-I is the major protein in HDL. Apo B-100 is the main protein on LDL and Lp(a), and apo B-48, which is produced from apo B-100 messenger RNA (mRNA) by an RNA editing process, is found on chylomicrons. Both apo B-100 and apo B-48 are found at one molecule per particle, are firmly bound, and do not exchange between particles, as the other apolipoproteins do. Apolipoproteins perform the following major functions: (1) modulate the activity of enzymes that act on lipoproteins, (2) maintain the structural integrity of the lipoprotein complex, and (3) facilitate the uptake of lipoprotein by acting as ligands for specific cell-surface receptors. Most apolipoproteins contain amphipathic helices, which are α -helices with one face containing hydrophobic amino acids and the other face containing polar or charged amino acids. This feature enables apolipoproteins to bind to lipids and still interact with the surrounding aqueous environment.

METABOLISM OF LIPOPROTEINS

Lipoprotein metabolism is commonly divided into (1) exogenous, (2) endogenous, (3) intracellular cholesterol transport, and (4) reverse cholesterol transport pathways.

Exogenous Pathway

The roles of the exogenous pathway—transport of dietary lipids from the intestine to the liver and peripheral cells—are largely mediated by chylomicrons (Fig. 23.17). Nascent chylomicrons, which are 90% triglycerides by mass, are first assembled by the microsomal transfer protein (MTP) in the endoplasmic reticulum of enterocytes by combining triglycerides and other lipids with apo B-48. Chylomicrons are secreted into the lymph and, after entering the circulation, acquire from HDL additional apolipoproteins, such as apo E, apo C-III, and apo C-II. Apo E is a ligand for uptake by the liver, whereas C-III inhibits hepatic clearance of lipoproteins and is also an inhibitor of lipoprotein lipase (LPL). In contrast, apo C-II is a potent activator of LPL,

which is attached to the luminal surface of endothelial cells and rapidly hydrolyzes the triglycerides on chylomicrons to free fatty acids. Liberated fatty acids are taken up by both a passive and active transport mechanism into muscle cells and other peripheral tissues as an energy source or by adipose cells for energy storage as triglycerides. As a consequence of lipolysis, chylomicrons are transformed into smaller chylomicron remnant particles, which are rapidly removed by the liver.

Endogenous Pathway

The function of the endogenous pathway is to transfer hepatically derived lipids, especially triglycerides, to peripheral cells for energy metabolism. It is mediated by the apo B-100-containing lipoproteins (Fig. 23.18). Hepatically derived lipids represent lipids that were synthesized by the liver or dietary lipids that were transferred to the liver by the exogenous pathway. VLDL, which contains approximately 55% triglycerides by mass and includes one molecule of apo B-100, is the principal apo B-containing lipoprotein that is secreted by the liver. As it

Reverse Cholesterol Transport Pathway

The function of the reverse cholesterol transport pathway is to remove excess cellular cholesterol from peripheral cells and return it to the liver for excretion. This process is largely mediated by HDL (Fig. 23.20). Cholesterol is actively pumped out of cells by the ABCA1 transporter onto lipid-poor apo A-I, which binds to lipid microdomains on the plasma membrane created by ABCA1. This process results in the formation of disc-shaped nascent HDL, which is made in the liver and in the intestine. Discoidal HDL then interacts with ABCA1 in peripheral cells, such as macrophages, and removes additional cholesterol. LCAT, which esterifies cholesterol on HDL, plays a key role in reverse cholesterol transport because cholesteryl esters are much more hydrophobic than cholesterol and remain trapped in the core of HDL until they are removed by the liver. The esterification of cholesterol on HDL converts the disc-shaped nascent HDL to spherical HDL. Spherical HDL, the main form of HDL in the circulation, acts as an

extracellular acceptor for cholesterol that may be removed from cells by other mechanisms besides ABCA1.

In the next stage of the reverse cholesterol transport pathway, the liver selectively removes cholesteryl esters from the lipid-rich spherical HDL via binding of the HDL to the SR-BI receptor and lets the lipid-depleted HDL return to the circulation for additional rounds of cholesterol removal from peripheral cells. CETP also plays an important role in this pathway because a significant fraction of cholesterol that is removed from cells by HDL is transferred as cholesteryl esters onto LDL by CETP and is eventually removed from the circulation by hepatic LDL receptors.

CLINICAL SIGNIFICANCE

The main clinical significance of lipids is primarily associated with their role in the development of **coronary heart disease** (CHD). CHD is a disease in which plaque builds up inside the coronary arteries that supply oxygen-rich blood to heart muscle.

Fig. 23.20 Reverse cholesterol transport pathway. *ABCA1*, ATP-binding cassette transporter A1; *ABCG1*, ATP-binding cassette transporter G1; *A-I*, apolipoprotein A-1; *B*, apolipoprotein B-100; *CE*, cholesterol ester; *CETP*, cholesteryl ester transfer protein; *FC*, free cholesterol; *HL*, hepatic lipase; *HDL*, high-density lipoprotein; *LCAT*, lecithin cholesterol acyltransferase; *LDL*, low-density lipoprotein; *LDL-R*, LDL receptor; *SR-B1*, scavenger receptor B-1; *TG*, triglyceride; *TICE*, transintestinal cholesterol excretion; *VLDL*, very-low-density lipoproteins.

Numerous studies have established that when total cholesterol and LDL cholesterol (LDL-C) concentrations are high, the incidence and prevalence of CHD are also high. In contrast to LDL-C, increased HDL cholesterol (HDL-C) concentrations have been shown to be protective for CHD in epidemiologic studies. Because atherosclerosis begins at an early age and can take decades to manifest clinically, measurement of plasma lipids and

lipoproteins is a valuable means of identifying individuals at risk for CHD and determining the most appropriate therapy.

Genetic Disorders of Lipoprotein Metabolism

Most patients with dyslipidemia do not have a single readily identifiable genetic mutation. Because of the complexity of lipoprotein metabolism, a multitude of environmental factors

Fig. 23.21 Algorithm from the ACC/AHA 2013 guidelines on the assessment and treatment of cardiovascular disease in adults. *To convert mmol/L, divide by 38.66. (Modified from Stone, N. J., Robinson, J. G., Lichtenstein, A. H., et al. [2014]. 2013 ACC/AHA guidelines on the treatment of blood cholesterol to reduce atherosclerotic cardiovascular risk in adults: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation*, 129[Suppl. 2], S1-S45.)

and common genetic polymorphisms that vary in importance, depending on the individual, probably account for most cases of hypercholesterolemia. Many secondary causes of dyslipidemia are a consequence of relatively common disorders or conditions (Table 23.7). Although rare, established genetic causes of dyslipidemia have been identified and are

illustrative of the role of lipid metabolism in the development of atherosclerosis.

Deficiency in Lipoprotein Lipase Activity

Deficient LPL activity due to mutations in the LPL gene is a rare autosomal recessive disorder characterized by

TABLE 23.7 Causes of Secondary Hyperlipidemia and Dyslipoproteinemia

Disorder	Cause
Exogenous	Drugs: corticosteroids, isotretinoin (Accutane), thiazides, anticonvulsants, β -blockers, anabolic steroids, certain oral contraceptives Alcohol Obesity
Endocrine and metabolic	Acute intermittent porphyria Diabetes mellitus Hypopituitarism Hypothyroidism Lipodystrophy Pregnancy
Storage disease	Cystine storage disease Gaucher disease Glycogen storage disease Juvenile Tay-Sachs disease Niemann-Pick disease Tay-Sachs disease
Renal	Chronic renal failure Hemolytic-uremic syndrome Nephrotic syndrome
Hepatic	Benign recurrent intrahepatic cholestasis Congenital biliary atresia
Acute and transient	Burns Hepatitis Acute trauma (surgery) Myocardial infarction Bacterial and viral infections
Others	Anorexia nervosa Starvation Idiopathic hypercalcemia Klinefelter syndrome Progeria (Hutchinson-Gilford syndrome) Systemic lupus erythematosus Werner syndrome

hyperchylomicronemia (type I pattern according to Fredrickson), with triglyceride concentrations reaching as high as 10,000 mg/dL (113 mmol/L). LPL is critical for the hydrolysis of triglycerides on chylomicrons and VLDL. This disorder is often first diagnosed in childhood, usually after recurrent episodes of severe abdominal pain and repeated attacks of pancreatitis. Eruptive xanthomas (a skin condition in which certain fats build up under the surface of the skin) and lipemia retinalis (a condition that occurs in patients when their plasma triglyceride concentrations exceed 2000 and 4000 mg/dL [22.6 to 45.2 mmol/L]) may be seen. The concentration of triglycerides often shows great fluctuation in response to diet and other factors that are not well understood. Individuals with this disorder are not predisposed to atherosclerotic disease, most likely because the chylomicron particles are too large to enter the vessel wall. The diagnosis is made by determination of LPL activity in plasma collected after heparin is

injected into patients to release the LPL that is bound to heparin sulfate and other glycosaminoglycans on the surface of endothelial cells.

Mutations in apo C-II, the main activator of LPL, also result in impairment of chylomicron catabolism, although this usually is less severe than with LPL gene mutations. The diagnosis of this rare autosomal recessive condition is made by demonstrating low LPL activity in postheparin plasma that is restored after the addition of apo C-II to the LPL assay mixture.

Familial Combined Hyperlipidemia

Familial combined hyperlipidemia (FCHL) is an autosomal dominant disorder that accounts for as many as 10% to 15% of individuals with premature CHD. Families with FCHL often have increased plasma concentrations of total and LDL-C (type IIa) or triglyceride/VLDL (type IV), or both (type IIb). Lipoprotein patterns also vary within an individual over time. In all cases, apo B-100 concentrations are increased because of overproduction. LDL particles in these patients tend to be small and dense because of a decreased lipid-to-protein ratio. LDL-C is usually only modestly increased to approximately 190 mg/dL (2.14 mmol/L), which is less than what is typically observed in heterozygous familial hypercholesterolemia (FH) (350 mg/dL; 3.95 mmol/L). The concentration of triglycerides usually is between 200 and 400 mg/dL (2.26 and 4.52 mmol/L) but may be significantly higher. The underlying genetic basis of FCHL is not known; it is mostly likely a polygenic disorder.

Familial Hypertriglyceridemia

Familial hypertriglyceridemia (FHTG) is an autosomal dominant disease characterized by a moderate increase in serum triglycerides. Overproduction of large VLDL particles with abnormally high triglyceride content is thought to be responsible for this disorder, but decreased lipolysis is sometimes a contributory factor. Because of the hypertriglyceridemia, plasma HDL-C is often notably decreased. This disorder is inherited in an autosomal dominant pattern with delayed expression, but it is a polygenic disorder with an estimated frequency in the population of approximately 1 in 500.

Type V Hyperlipoproteinemia

Type V hyperlipoproteinemia is characterized by an increase in both chylomicrons and VLDL and typically presents in adults. It is very common that acute pancreatitis develops subsequent to the massive hypertriglyceridemia (in the range of 1000 to 2000 mg/dL; 11.3 to 22.6 mmol/L). Type V HLP may also result from an inherited disorder that has an incidence of approximately 1 in 500. The disease appears to be an autosomal dominant disorder with increased production and/or decreased removal of VLDL. The activity of LPL in these individuals may be normal or low, and the plasma concentration of apo C-II is normal. Clinical presentations include (1) eruptive xanthomas, (2) lipemia retinalis, (3) pancreatitis, and (4) abnormal glucose tolerance. Most of these patients have a modestly increased risk of cardiovascular disease.

Dysbetalipoproteinemia (Type III)

Dysbetalipoproteinemia, also called *type III hyperlipoproteinemia* or remnant removal disease, is an autosomal recessive disorder caused by a defect in the removal of lipoprotein remnants from both chylomicrons and VLDL. Apo E present on the surface of lipoprotein remnant particles interacts with specific hepatic receptors and facilitates the removal of these particles. Apo E exists in three common polymorphisms or variants, designated E₂, E₃, and E₄. Some individuals with dysbetalipoproteinemia are homozygous for the apo E₂ isoform, which does not efficiently bind to hepatic remnant receptors, thus leading to accumulation of remnant particles. Although rare, genetic mutations in the *APOE* gene have been associated with the disorder. The remnant particles that accumulate are enriched in cholesterol, have a density less than 1.006 g/mL, and are commonly referred to as β -VLDL, or floating β -lipoprotein. Dysbetalipoproteinemia has a late onset and may manifest in patients with a secondary cause of dyslipidemia or obesity. The most distinctive clinical feature of dysbetalipoproteinemia is the presence of palmar xanthomas—yellow fat deposits in the creases of the palms. Tuberos and tuberoeruptive xanthomas may also occur but are not unique to this syndrome. Premature atherosclerosis commonly develops, particularly in the lower extremities. The incidence of dysbetalipoproteinemia is approximately 0.1% in the general population. However, apo E₂ homozygosity is seen in approximately 1% of the population in North America; thus the occurrence of defective alleles is necessary but not sufficient to produce the disorder.

Familial Hypercholesterolemia

FH is caused by defects in the LDL receptor pathway, which binds and removes LDL from the circulation. LDL thus accumulates in the plasma, resulting in its increased deposition in the skin, tendons, and arteries, where it causes atherosclerosis. LDL particles tend to be larger and carry increased amounts of cholesterol. Triglyceride concentration may be normal or only slightly increased, and HDL-C concentration is slightly decreased. Most of these patients have gene defects in the LDL receptor gene (*LDL-R*). Less commonly, defects in two other genes, *RHOA* (formerly called *ARH-1*) and *PCSK9*, which code for proteins involved in internalization or processing of the LDL receptor, may cause FH. Mutations in the LDL receptor gene (*LDL-R*) and in *PCSK9* are inherited in an autosomal codominant pattern. Homozygous FH patients are severely affected, whereas heterozygotes usually have a milder phenotype but are still clinically affected usually at a later age. Defects in *RHOA* are inherited in an autosomal recessive pattern.

Heterozygous FH due to mutations in the LDL receptor gene is one of the most common genetic disorders, with an estimated incidence of 1 in 500 in the United States. The mean plasma LDL-C in children and adult heterozygotes is usually 2 to 3 times that of normal individuals, whereas LDL-C of homozygotes is usually fourfold to sixfold above normal. In heterozygotes, xanthomas appear toward the end of the second decade of life, and clinical manifestations

of atherosclerotic disease often are noted during the fourth decade. In homozygotes, cutaneous xanthomas often develop by 4 years of age, if they are not already present at birth. Left untreated, death from myocardial infarction generally occurs in homozygotes before the end of the second or third decade of life.

Familial Defective Apolipoprotein B-100

Familial defective apo B-100 is an autosomal dominant disorder, the result of mutations in the gene *APOB*, which reduce its affinity for the LDL receptor. LDL-C is increased, but triglycerides and HDL-C are usually within reference intervals. Like those with FH, these individuals have an increased incidence of CHD, but overall, the dyslipidemia in this disorder is less aggressive than in FH. Clinical differentiation between this disorder and heterozygous FH is sometimes difficult, but management of the two disorders is similar. The frequency of this mutation is 1:500 to 1:600 in hypercholesterolemic individuals from populations of European descent, but it is very rare in non-Europeans.

Hypoalphalipoproteinemia

Hypoalphalipoproteinemia, or low HDL-C, is caused by several genetic defects and is often but not always associated with an increased incidence of CHD. Mutations or deletions of the *APOA1* gene are a rare cause of hypoalphalipoproteinemia. *LCAT* deficiency is also associated with low HDL. These patients often have cloudy corneas as a result of infiltration of lipid, as well as renal disease because of the production of abnormal lipoprotein particle called LpX that becomes trapped in the glomerulus.

Tangier disease is a rare autosomal recessive disorder that is associated with a notable reduction in HDL. The major clinical signs of Tangier disease are (1) hyperplastic orange tonsils, (2) splenomegaly, and (3) peripheral neuropathy. Deposition of cholesteryl esters is increased in various tissues of the body, particularly macrophages, which form foam cells. Tangier disease is caused by mutations in the *ABCA1* gene for the *ABCA1* transporter, which mediates the first step of the reverse cholesterol transport pathway—efflux of cholesterol from cells (see Fig. 23.20).

Sitosterolemia

Sitosterolemia is a rare inherited disease characterized by overabsorption of dietary sitosterol and increased hepatic secretion of sitosterol. Consequently, cholesterol synthesis and elimination are altered and cholesterol levels are increased. Homozygotes for this defect have increased plasma sitosterol concentrations (requiring highly specialized laboratory measurement), xanthomas, and very early onset of atherosclerotic cardiovascular disease (ASCVD).

Lp(a) and LpX

There are two forms of hyperlipidemia not covered by the Fredrickson classification: increase in Lp(a) and the presence of LpX. The size variation in Lp(a) and consequently the level of Lp(a) is largely determined by the variant copy

numbers of “kringle” repeats in the APOA gene that encodes apo(a). Elevated Lp(a) concentrations impose increased risk of ASCVD and calcific aortic valve diseases. Populations of African descent are shown to have higher Lp(a) levels than do other populations, although it may not correspond to an increased risk of heart diseases. Markedly elevated Lp(a) also tends to run in certain families, but the inheritance pattern is not clearly defined.

LpX is produced in severe obstructive biliary tract diseases as an abnormal lipoprotein. It appears that when the neutral cholesteryl esters are insufficient to form a lipid core in lipoproteins, LpX is generated. It has a phospholipid bilayer instead of the single phospholipid layer in normal lipoproteins, and it lacks apo B-100 that is present on other lipoproteins in the endogenous pathway, which may confound the measurement or calculation of cholesterol fractions.

ADULT MANAGEMENT OF LIPOPROTEIN DISORDERS

The initial diagnosis of a dyslipoproteinemia and determination of the best treatment approach for a patient have been based largely on measurements of (1) total cholesterol, (2) triglyceride, (3) HDL-C, and (4) LDL-C; this is commonly referred to as a *lipid panel*. However, lipid and lipoprotein test results must be interpreted in the context of a medical history. Medical history and other laboratory test results are also important for determining whether a dyslipoproteinemia is the result of a primary lipoprotein disorder or is a consequence of one or more of the secondary causes of hyperlipidemia (see Table 23.7), which, if present, should also be addressed. In contrast to most other laboratory tests, hypercholesterolemia is defined on the basis of findings from epidemiologic studies that were used to establish a desirable concentration for reducing CHD risk (Table 23.8), rather than a reference study of normal individuals. Cholesterol screening is recommended

TABLE 23.8 Adult Treatment Panel (ATP) III Classification of Low-Density Lipoprotein, Total, and High-Density Lipoprotein Cholesterol (mg/dL)

LDL cholesterol	<100	Optimum
	100–129	Near or above optimum
	130–159	Borderline high
	160–189	High
	≥190	Very high
Total cholesterol	<200	Desirable
	200–239	Borderline high
	≥240	High
HDL cholesterol	<40	Low
	≥60	High

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285, 2486–2497.

every 5 years for all adults older than 20 years and should involve measurements of fasting (1) total cholesterol, (2) triglyceride, (3) HDL-C, and (4) calculated or measured LDL-C. If a fasting sample is not available initially, only total cholesterol and HDL-C should be considered.

Next, an assessment should be made of the risk for CHD. This is based on clinical evidence of existing CHD or the presence of conditions that are closely associated with CHD, such as (1) symptomatic carotid artery disease, (2) peripheral vascular disease, and (3) abdominal aortic aneurysm, which are called *CHD risk equivalents*. Risk assessment for CHD is also based on the presence of known risk factors for CHD, such as (1) hypertension, (2) smoking, and (3) family history (Box 23.1).

Therapeutic lifestyle changes (Box 23.2) serve as the cornerstone of therapy for lipid disorders. The concentration of LDL-C is used both to decide the most appropriate therapy and to monitor the effectiveness of treatment. Adult

BOX 23.1 Major Risk Factors (Exclusive of Low-Density Lipoprotein Cholesterol)

- Cigarette smoking
- Hypertension (blood pressure ≥140/90 mm Hg or on anti-hypertensive medication)
- Low HDL cholesterol (<40 mg/dL)¹
- Family history of premature CHD (CHD in male first-degree relative <55 years; CHD in female first-degree relative <65 years)
- Age (men ≥45 years; women ≥55 years)

CHD, Coronary heart disease; HDL, high-density lipoprotein.

Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285, 2486–2497.

BOX 23.2 Therapeutic Lifestyle Changes for the Prevention of Coronary Heart Disease

- Diet
 - Saturated fat <7% of calories, cholesterol <200 mg/day
 - Consider increased viscous (soluble) fiber (10–25 g/day) and plant stanols/sterols (2 g/day) as therapeutic options to enhance LDL lowering
- Weight management
- Increased physical activity

^aHDL cholesterol ≥60 mg/dL counts as a “negative” risk factor; its presence removes one risk factor from the total count.

HDL, High-density lipoprotein; LDL, low-density lipoprotein.

Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive Summary of the Third Report of the National Cholesterol Educational Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*. 285, 2486–2497.

treatment guidelines for hypercholesterolemia are illustrated in Table 23.9. Note that aggressiveness of treatment depends on the risk category of the patient and his or her starting LDL-C concentration. Patients at highest risk for CHD (10-year risk >20%) and those who already have clinical evidence of CHD or a CHD risk equivalent have the lowest LDL-C treatment threshold and the lowest LDL-C target goal. Ideally, for such patients, LDL-C should be less than 100 mg/dL (2.59 mmol/L) after therapy; this will likely involve some type of drug treatment. Patients in an intermediate risk category (10-year risk <20%) have a higher concentration for their LDL-C target goal and in some cases, depending on their starting LDL-C, may be treated only by therapeutic lifestyle changes. For patients in the lowest risk category (0 to 1 risk factors), desirable LDL-C is less than 160 mg/dL (4.14 mmol/L), and drug therapy should be considered only if initial LDL-C is greater than 190 mg/dL (2.15 mmol/L). Specific recommendations have been put forth for the frequency of monitoring lipids and lipoprotein tests and for when drug therapy should be tried for patients who do not reach their LDL-C target treatment goals with just therapeutic lifestyle changes.

Increased triglycerides and low HDL-C are considered conditions that independently alter the risk for CHD and may alter the recommended treatment. However, in both cases the primary goal of therapy should be to lower LDL-C and secondarily to improve the increased triglycerides or low HDL, if these conditions persist after LDL-C is lowered. Each patient at risk for CHD should also be assessed for the presence of metabolic syndrome and should be treated for underlying causes and associated symptoms. Other newly developed lipoprotein tests, such as (1) Lp(a), (2) remnant lipoproteins, and (3) small dense LDL, and other markers, such as (4) C-reactive protein (CRP), and (5) homocysteine, may also be valuable in CHD risk stratification, particularly for patients who are at borderline or intermediate risk, based on conventional lipid and lipoprotein tests.

A wide variety of pharmacologic agents for cholesterol lowering in adults are prescribed individually or in combination to lower LDL-C, including (1) bile acid-binding resins (cholestyramine and colestipol), (2) niacin, (3) gemfibrozil,

(4) ezetimibe, and (5) HMG-CoA reductase inhibitors (e.g., atorvastatin, fluvastatin, lovastatin, pravastatin, rosuvastatin, simvastatin, pitavastatin); agents in the latter group have been found to reduce LDL-C by as much as 40%. Some of these drugs are better tolerated by individual patients than others; all have demonstrated long-term safety in adults and have been shown to decrease CHD risk. Niacin has been the most effective therapy for raising HDL-C, but the value of raising HDL-C has been called into question by trials of the CETP inhibitors, which dramatically increase HDL-C but have not decreased CHD events. Monoclonal antibody therapy against PCSK9 has recently been approved and results in significant decreases of LDL-C even for patients already treated with statins. Because of the expense of this therapy, it is recommended only for statin-intolerant patients and or patients with severe dyslipidemias that are not adequately controlled on conventional drug therapy. Niacin, fibrates, and fish oil can also lower plasma triglycerides but so far have not been shown to be useful for reducing CHD events but should be considered in patients with severe hypertriglyceridemia who are at risk for pancreatitis.

In 2013 the National Heart, Lung, and Blood Institute (NHLBI) passed the mission of cardiovascular guideline production to a new task force from the American College of Cardiology/American Heart Association (ACC/AHA), which issued new recommendations on the “Treatment of Blood Cholesterol to Reduce Atherosclerotic Cardiovascular Risk in Adults” on “the Assessment of Cardiovascular Risk,” and “for the Management of Overweight and Obesity in Adults.” The new statement (Fig. 23.21), which for the most part considered only level I evidence from randomized, blinded, clinical trials and not expert opinion, eliminated numerical treatment targets for LDL-C and non-HDL-C and introduced a new pooled risk calculator for treatment initiation decisions based on cardiovascular disease, which includes not only CHD but also stroke and peripheral vascular disease. The new risk calculator also has a separate algorithm for African Americans. Patients deemed to be at high risk for CHD, including those with an LDL-C greater than 190 mg/dL (4.91 mmol/L), are advised to initiate lifestyle changes and drug therapy, defined as high-dose

TABLE 23.9 Low-Density Lipoprotein Cholesterol Goals and Cut Points for Therapeutic Lifestyle Changes and Drug Therapy in Different Risk Categories

Risk Category	LDL Goal (mg/dL)	LDL Concentration at Which to Initiate Therapeutic Lifestyle Changes (mg/dL)	LDL Concentration at Which to Consider Drug Therapy (mg/dL)
CHD or CHD risk equivalents (10-year risk >20%)	<100	≥100	≥300 (100–129; drug optional)
2+ risk factors (10-year risk ≤20%)	<130	≥130	10-year risk 10%–20%: ≥130 10-year risk <10%: ≥160
0–1 risk factor (10-year risk <10%)	<160	≥160	≥190 (160–189; LDL-lowering drug optional)

CHD, Coronary heart disease; LDL, low-density lipoprotein.

Modified from Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285, 2486–2497.

statin in an attempt to reduce LDL-C by 50% from baseline (see Fig. 27.21). Other high-risk groups that are potential candidates for high-dose statins (or moderate dose if they cannot tolerate high-dose statins) are patients with preexisting cardiovascular disease (CVD), and diabetic patients (ages 40 to 75). Primary prevention patients, between age 40 and 75 years, who do not fall into one of these high-risk categories should have their 10-year CVD risk calculated and should be treated with high- or moderate-dose statins if the risk is greater than 7.5% and treated with moderate-dose statins if their 10-year CVD risk falls between 5% and 7.5%. Primary prevention patients with a 10-year risk of less than 5% or if they fall outside the age range for the risk calculator (<40 years or >75 years) are generally not recommended for statin therapy but could be considered for lifestyle changes and or statin therapy, depending on other considerations, such as a strong family history of premature CVD or the results of ancillary testing, such as high-sensitivity C-reactive protein (hsCRP). Compared with the previous Adult Treatment Panel guidelines, it is estimated that significantly more patients will be now treated with statins by the new ACC/AHA guidelines but some younger patients who would appear to be at risk, based on the older guidelines, would no longer be treated. Follow-up laboratory testing is recommended by the new guidelines only to judge compliance and to ensure that at least 50% reduction in LDL-C is achieved. Specific cholesterol treatment goals for LDL-C and non-HDL-C are no longer advised. Overall, use of nonstatin therapies is also discouraged by these new guidelines, although this may change in the future with new information, such as clinical trials that show that ezetimibe added to statin was more efficacious compared with statin monotherapy in reducing cardiovascular events in an acute coronary syndrome setting. There was no specific guidance on the management of patients with moderate to high triglycerides or increased Lp(a). The ACC/AHA statement also took no position for or against using apolipoprotein B, LDL-particle number, or Lp(a). However, other national and international organizations have included other CVD biomarkers in their lipid and lipoprotein recommendations, particularly for patients at intermediate risk. Furthermore, other organizations, such as National Lipid Association and American Association of Clinical Endocrinology did not endorse the ACC/AHA guidelines and have published their own guidelines.

Management of Lipoprotein Disorders in Pediatrics

Because the process of atherosclerosis begins in children, and CHD risk factors that start in childhood, such as obesity and dyslipidemia, often persist into adulthood, it is important to identify children at risk for CHD, with the expectation that early intervention will be the most effective way to prevent future disease. This goal has to be tempered by the concern that unlike in adults, clinical studies supporting the long-term effectiveness and safety of any type of therapy, particularly the use of lipid-lowering medications in children, are limited.

The 2001 guidelines for cardiovascular health and risk reduction in the pediatric population from NHLBI are

integrated guidelines that make age-specific recommendations on the multiple risk factors that contribute to CHD. They are aimed at primary care physicians and other health professionals who treat children. They provide guidance not only on the diagnosis and management of dyslipidemias but also on how to monitor (1) family history, (2) tobacco exposure, (3) degree of physical activity, (4) diet, (5) growth charts, (6) blood pressure, and (7) diabetes, as well as (8) how to educate children and parents on healthy lifestyles.

Previous guidelines did not recommend universal lipid testing and instead relied upon identifying children at risk on the basis of family history of CHD or dyslipidemia. Although family history integrates (1) genetic, (2) behavioral, and (3) environmental factors, it is often inadequate and has been shown to miss as many as half of children at risk for CHD. Current guidelines recommend universal lipid screening between ages 9 and 11 years and then later between 18 and 21 years of age. Age 9 to 11 years was chosen because lipids often change after puberty and because this is the age at which children with severe lipid disorders should first be considered as possible candidates for drug therapy. Age 18 to 21 years was chosen as a second time to screen because some lipid disorders do not become manifest until late teenage years or young adulthood and because after this point in time, many individuals may not participate in lipid screening until many years later, when advanced disease has already developed. Because it is more convenient, particularly for young children, it is recommended that a nonfasting sample be analyzed to determine non-HDL-C; calculated as total cholesterol minus HDL-C and has been shown in both children and adults to be just as effective as LDL-C as a CHD risk marker. For other age groups, lipid testing is recommended on a fasting sample, only if children have a strong family history of CHD and/or have a parent with a dyslipidemia or a condition that puts them at high risk for CHD, such as diabetes.

As in adult guidelines, recommended interventions are calibrated to the degree of CHD risk; lifestyle changes, such as low-fat diet and increasing physical activity, are recommended first for all patients (Fig. 23.22). If, after a 3-month period, lifestyle changes prove ineffective in reaching the LDL-C target goal, which varies depending on the overall risk, then drug treatment with a statin and/or a bile acid sequestrant should be considered for children 10 years of age or older. All children, even those younger than age 10 years, who present with a marked increase in serum lipids (LDL-C >250 mg/dL [6.46 mmol/L]) may have a genetic lipid disorder, should be referred to a lipid specialist and may require additional types of drugs or other treatment approaches, such as LDL apheresis in the case of FH. Because of the high prevalence of obesity in the pediatric population, the most common pattern of dyslipidemia in children consists of (1) a moderate to severe increase in triglycerides, (2) a mild increase in LDL-C, and (3) decreased HDL-C. In general, patients respond well to changes in diet and weight loss and often do not require drug therapy. Children who present with a marked increase in triglycerides to greater than 500 mg/dL (>5.65

Fig. 23.22 Model of steps in therapeutic lifestyle change. *LDL*, Low-density lipoprotein. (Modified from Executive summary of the third report of the Expert Panel on Blood Cholesterol Levels in Children and Adolescents, National Cholesterol Education Program. Lipid Metabolism Branch, Division of Heart, Lung, and Blood Institute. NIH Publication No. 01-3670. US Department of Health and Human Services, Public Health Service, National Institutes of Health. Bethesda, MD: National Institutes of Health, 2003.)

mmol/L) may have a primary genetic defect, such as LPL deficiency, are at risk for pancreatitis and should be seen by a lipid specialist. It is recommended that children treated with lipid-lowering drugs start with the lowest possible dose; when placed on statins, hepatic transaminases and creatine kinase should be measured to monitor for hepatic and muscle toxicity (Fig. 23.23). Decisions about placing a child on a lipid-lowering drug should be based on an average of at least two fasting serum lipid profiles that are at least 2 weeks apart but no more than 3 months apart.

ANALYSIS OF LIPIDS, LIPOPROTEINS, AND APOLIPOPROTEINS

As risk-related cutoff points (see Table 23.9) were developed, much effort has gone into improvement and standardization of lipid and lipoprotein assays to ensure their proper performance (Table 23.10) and to ensure comparability of test results between different methods and different clinical laboratories, thus reducing misclassification of patients' CHD risk.

Currently, worldwide, the policy that most laboratories follow is an overnight fast of a minimum of 8 hours prior to obtaining samples for testing the lipid profile. The European Atherosclerosis Society/European Federation of Clinical Chemistry and Laboratory Medicine (EAS/EFLM) recently published a consensus statement promoting the use of non-fasting lipid profiles for the assessment of cardiovascular disease risk. The rationale for the EAS/EFLM stance is ease of collection and greater compliance in patient preparation for lipid testing. This statement addresses the perceived limitations of testing nonfasting samples by referencing data from studies that evaluated lipid variation in postprandial versus fasting states; showing that there is no change in HDL-C, apo A1, apo B, or Lp(a) and minimal changes in triglycerides,

total cholesterol, calculated remnant cholesterol, non-HDL-C, and LDL-C. In addition, the publication addresses the influence of the postprandial state on the assessment of cardiovascular disease risk by citing studies where various nonfasting lipid parameters were monitored relative to clinical outcomes.

Cholesterol Assays

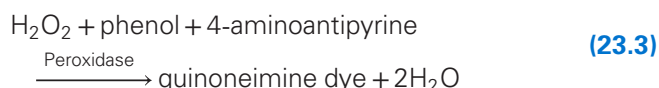

Enzymatic methods have become the assays of choice for the routine measurement of cholesterol. A commonly used three-step procedure is shown later. Enzyme reagents are mixed with serum or plasma and are incubated under controlled conditions for color development; absorbance is measured in the visible portion of the spectrum, generally at approximately 500 nm. The reagents typically use a bacterial cholesteryl ester hydrolase to cleave cholesteryl esters:

The 3-OH group of cholesterol is then oxidized to a ketone in an oxygen-requiring reaction catalyzed by cholesterol oxidase:

H₂O₂ is measured in a peroxidase-catalyzed reaction that forms a colored dye:

Fig. 23.23 Algorithm for assessment of coronary heart disease risk in children based on lipid screening. *For ages 19–21, non-HDL-C ≥ 190 mg/dL is the recommended cut point. FHx(+), Positive family history; FLP, fasting lipid profile; RF, risk factor. Other positive risk factors or risk equivalents for cardiovascular disease include RF(+). ALT, Alanine aminotransferase; AST, aspartate aminotransferase; CK, creatine kinase. (Modified from Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents; National Heart, Lung, and Blood Institute. [2011]. Expert Panel on Integrated Guidelines for Cardiovascular Health and Risk Reduction in Children and Adolescents. Summary report. *Pediatrics*, 128, S1–S44.)

TABLE 23.10 National Cholesterol Education Program Recommendations for Analytical Performance of Lipid and Lipoprotein Measurements

	Total Error (%)	CONSISTENT WITH	
		Bias (%)	CV (%)
Cholesterol	8.9	≤±3	≤3
Triglycerides	≤15	≤±5	≤5
HDL cholesterol	≤13	≤±5	≤4
LDL cholesterol	≤12	≤±4	≤4

CV, Coefficient of variation; HDL, high-density lipoprotein; LDL, low-density lipoprotein.

Enzymatic methods are subject to interference from other colored compounds or from those that compete with the oxidation reaction, such as (1) bilirubin, (2) ascorbic acid, and (3) hemoglobin. Assays are usually linear up to approximately 600 to 700 mg/dL (15.54 to 18.13 mmol/L).

Triglycerides

Triglycerides are also routinely measured with enzyme reagents. Several different enzyme sequences have been used. With all of these methods, the first step is the lipase-catalyzed hydrolysis of triglycerides to glycerol and fatty acids

Glycerol is then phosphorylated in an ATP-requiring reaction catalyzed by glycerokinase:

With the most commonly used methods, glycerophosphate is oxidized to dihydroxyacetone and H_2O_2 in a glycerophosphate oxidase-catalyzed reaction:

and H_2O_2 formed in the reaction is measured as described in reaction (3).

Enzymatic triglyceride methods are fairly specific in that they do not detect glucose or phospholipids. They are linear in the concentration range up to approximately 700 mg/dL (7.91 mmol/L) and, when automated, are operated with coefficients of variation (CVs) in the range of approximately 2% to 3%. Because glycerol is a product of normal metabolic processes, it is present in serum. Thus the measured quantity of triglycerides in serum is overestimated slightly, if not corrected for endogenous glycerol. In healthy individuals, endogenous glycerol represents the equivalent of less than 10 mg/dL (0.11 mmol/L) of triglyceride; therefore the error due to glycerol is not usually clinically significant. Some laboratories use an alternative triglyceride assay, in which the endogenous glycerol is first “blanked out” by adjustment of the calibrators to compensate for an average bias or by enzymatic consumption of glycerol in a prereaction step before triglycerides are measured.

High-Density Lipoprotein Cholesterol

The concentration of cholesterol associated with HDL is determined after the non-HDL lipoproteins are physically removed or effectively masked.

Traditionally, non-HDL lipoproteins—VLDL, IDL, Lp(a), LDL, and chylomicrons—were precipitated with polyanions. Polyanions react with positively charged groups on lipoproteins, and this interaction is further facilitated in the presence of divalent cations, such as magnesium, to create a precipitate. The precipitate is removed by centrifuging for at least 45,000 g-minutes, and cholesterol is measured enzymatically in the supernatant. Several polyanion-divalent cation combinations have been used, including (1) heparin sulfate– MnCl_2 , (2) dextran sulfate– MgCl_2 , and (3) phosphotungstate– MgCl_2 . HDL-C assays are considered inaccurate in samples containing triglyceride concentrations greater than 400 mg/dL (4.52 mmol/L).

Direct HDL-C assays, also known as *homogeneous assays*, are most commonly used to measure HDL-C. In contrast to precipitation-based assays, no physical separation of HDL from non-HDL fractions occurs. Instead, HDL-C is selectively measured by effective masking or promoting the consumption of cholesterol from non-HDL fractions so that it does not react with the enzymes used to measure cholesterol on HDL. This is achieved by a variety of methods, depending on the type of assay. For example, some assays involve the use of antibodies or various polymers or complexing agents, such as cyclodextrin, that shield the cholesterol in the non-HDL fractions from reacting with cholesterol-measuring enzymes. Some assays depend on modifications of cholesteryl esterase and cholesterol oxidase that make them more selective for HDL-C. Finally, some assays use a blanking step that enzymatically consumes cholesterol from non-HDL fractions. Unlike the precipitation HDL-C assays, no sample pretreatment step is performed with direct assays and thus they can be fully automated. However, these assays sometimes show relatively poor performance compared with reference methods on dyslipidemic samples, particularly those with high triglycerides.

Low-Density Lipoprotein Cholesterol

Until recently, LDL-C was determined indirectly. In the most widely used indirect method, (1) total cholesterol, (2) triglycerides, and (3) HDL-C are measured in a fasting sample, and LDL-C is calculated from the primary measurements by the empirical Friedewald equation:

$$\text{LDL-C} = [\text{Total cholesterol}] - [\text{HDL Cholesterol}] - [\text{Triglycerides}]/5 \quad (23.7)$$

where all concentrations are given in milligrams per deciliter. Triglycerides/2.22 is used when LDL-C is expressed in millimoles per liter. The factor (triglycerides)/5 is an estimate of the VLDL cholesterol concentration and is based on the average ratio of triglycerides to cholesterol in VLDL.

In practice, the Friedewald equation should not be used (1) in samples that have triglyceride concentrations greater than 400 mg/dL (4.52 mmol/L), (2) in samples that contain significant quantities of chylomicrons (nonfasting specimen), (3) in patients with dysbetalipoproteinemia, and (4) in patients with low total cholesterol (LDL <70 mg/dL). In these cases the factor (triglyceride)/5 does not provide an accurate estimate of VLDL cholesterol, and this leads to large errors in calculated LDL-C. As with HDL-C, several methods are now used for the direct measurement of LDL-C. In general, these assays yield results similar to those obtained by calculating LDL-C and performing the β -quantification reference method, which is based on ultracentrifugation, but performance may not be as good on high-triglyceride samples. Evidence suggests that different direct assays may not be specific and may include some of the other apo B-containing lipoproteins or may miss some LDL subfractions, such as the more atherogenic small, dense LDLs.

Measurement of Apolipoproteins

Immunoturbidimetric and immunonephelometric assays are typically used in measuring apo A-I and apo B-100 (see Chapter 15 for additional information on these techniques). Alternatively, more sensitive techniques, such as enzyme-linked immunosorbent assay (ELISA) and radioimmunoassay (RIA), are usually more suitable for apolipoproteins that are present in significantly lower concentrations, such as apo C-I and apo C-II. Considerable effort has been expended in the past to standardize apo A-I and B-100 measurements, leading to significant improvement in the overall performance of these assays, but they are still not widely used for CHD risk assessment. Tests for apo B-100 and apo A-I are now well standardized and calibrated to World Health Organization reference materials. Immunoassays for total apo E are not commonly done, but genotyping of apo E is used to identify the apo E₄ isoform, which is associated with increased cholesterol and risk for Alzheimer disease.

Lipoprotein(a)

Although Lp(a) particles typically carry only a relatively small fraction of total cholesterol, these lipoprotein particles are
